The lengthening of the course of lectures in our medical colleges, the preliminary terms, the spring courses, the post-graduate schools, and the increased popularity of spring and summer schools, all attest to the need of some system of medical instruction to supplant the medical preceptor. But this increasing of the length of the college term and number of courses required for graduation has only served to call attention to the defects of the didactic lecture system of medical instruction. The course of medical lectures has gradually been increased from three or four to five or six months. Most schools have made

provision for a third or even a fourth course of lectures, and quite a large number of schools have made a third course a requisite for graduation. It was an imposition upon the medical student to compel him to listen to the same course of lectures twice; but to compel him to take the same dose the third or fourth time is more than even a medical student, who is expected to patiently bear all sorts of indignities, should be called upon to endure. The remedy for this anomalous position in which the medical colleges find themselves situated is easily found. It is the *graded course*. But the remedy is easier discovered than applied. In order to successfully conduct a three years' graded course the number of hours devoted to teaching must be trebled; either every professor must devote three hours a day to teaching, whereas formerly he gave but one, or the number of teachers must be increased threefold. In the former case the college must be endowed, or the fees greatly increased, as but few teachers could give the amount of time requisite for the merely nominal compensation which the average medical college professor now receives. In the latter case, if a sufficient number of teachers are employed, the quality of the institution must suffer from putting inferior men in the responsible position of teacher. A few years since the announcement of the Medical Department of the University of Pennsylvania, a graded school, contained one hundred and thirty-one names of professors, lecturers, and assistants. The same year the announcement of Jefferson Medical College, an ungraded school, contained less than twenty names of professors, clinical assistants, and other instructors. These two announcements illustrate very graphically the requirements of the two systems of education as to the number of teachers employed.

It is pleasing to note that those schools which have adopted the graded course of instruction "have every reason to feel gratified at the result attained." I believe that it is only a question of a few years until every medical school will be obliged to adopt a graded course of some kind in deference to public opinion.

The late Professor Gross, speaking of the class of 1877 in Jefferson Medical College, says: "It is lamentable to think how imperfect the whole system of medical education is in this country. Our students are driven from one lecture to another, hour after hour, like so many cattle, and the wonder is that when they come up for their final examination at the close of the session, they have any knowledge at all of a fixed or definite character. The fact is, much of what the student is taught in the early part of the session is knocked out of him before the close. He gets a daily surfeit from the beginning to the end, and the consequence is that his knowledge is vague and imperfect in every branch of his studies."

"Of the two hundred and three candidates for graduation fourteen were suspended. They were re-examined, and all passed but five!"

In a recent address on surgery as a science and an art, Dr. Frothingham, of Ann Arbor, said: "Didactic lectures, instituted in the days when books were few and costly, by the power of conservatism, have already held their place of prominence longer than they should. They have outlived their period of usefulness, and seem to serve for the entertainment of indolent students more than they do the purpose of thorough education in such a branch as surgery."

Dr. Dutton, previous to this, asked, in the *Cleveland Medical Gazette*, "whether the time has not fully come when the attention of the medical profession should be called to methods of medical teaching. In all our colleges didactic lectures occupy the time for the most part. Clinics and quizzes are sandwiched in, but the published time schedules, which fairly represent the plans pursued in all or nearly all the courses of study, show that lectures (so-called) are the sources from which the student is expected to acquire professional knowledge. On five or sometimes six days of the week he is required to listen to these from four to seven hours daily, with the exception of the few minutes allowed, between lectures, for change of teachers or lecture rooms. Why should medicine be taught in this miscellaneous way, while in all other departments of scientific instruction primary importance is attached to classification? May it not be proper also to enquire whether it is profitable for any student, of whatever mental capacity, to pursue so many branches of study at once? Those most familiar with teaching tell us that three solid studies are as many as can be pursued at once in other schools, and the courses of studies in our scientific and literary institutions everywhere are arranged on this plan. By what principle do we make medicine exceptional in this respect? Might not the professors in our medical colleges learn much to their profit by consulting more frequently those who have studied more specifically the principles and art of teaching? More lectures are given now than formerly, where fewer might be better. The stuffing processes are the same now as ever. The student is seldom expected to *prepare* a lesson. He has no time. He often cannot know the topic even of the next hour. Nor has he time to review carefully a lecture after he has heard it. He frequently does not so much as own or have access to the books which treat of many subjects presented to him, His preparatory studies with his preceptor have, in many instances, been pursued also in a desultory way. Preceptors *precept* very little, and the facts are that medical students, as a rule, from the time they enter a preceptor's office until they are honoured by their M.D. degree, have little opportunity to receive careful, methodical, scientific teaching."

If the time has come when the preceptor must go, when the didactic lecture must go, what system of medical education must be adopted? I think that it is the belief of everyone who has given the subject much thought, that most subjects, such as chemistry, anatomy, physiology, and materia medica, should be taught by recitations, laboratory work, and "quizzes," the same methods that have proved most satisfactory in other educational institutions. The course of instruction must be increased from five or six to ten or twelve months, and not less than three years of such instruction must be necessary for graduation. Clinical teaching must be made a more prominent feature in all our medical schools.

Such a radical change as this contemplates cannot be made at once. It must be of gradual growth. It will require greater facilities for laboratory, microscopical, and experimental research than medical colleges now possess. It will necessitate a large corps of teachers who devote their entire time to teaching. This will necessitate large endowments, such as none of our medical colleges now have. If this, then, be true, we cannot at once give up all that has proved of value in the past; we must make the best of such material and advantages as we have at our command.

Dr. Billings says that in the discussion of medical education, "it seems to be often assumed that all physicians

should have the same qualifications and be educated to the same standard, which, in one respect, is like saying they should all be six feet high, and, in another, is like the army regulations which prescribe the same rations and allowance of clothing for Maine and Florida, Alaska and Oregon. A young and energetic man who has spent six years in obtaining a university education, and four more in the study of medicine as it ought to be studied, that is to say, in preparing himself to study and investigate the rest of his life, will not settle in certain districts. He has invested ten years' labour and from five to ten thousand dollars, and a locality which will give him a maximum income of perhaps fifteen hundred dollars per annum will not be satisfactory; in part, because the capital should bring a better interest; in part, because he will have acquired tastes which will make his life unpleasant in such places. Yet these places must have physicians of some sort, and it is not clear as to how they are to be supplied if some of the universal and extreme reforms in medical education which have been proposed are to be enforced."

The old system of medical preceptors and didactic lectures has not proven a complete failure, notwithstanding all that has been said against it by friends and enemies alike.

The medical profession in the United States compares favourably with that of other countries, in which the period devoted to medical study is from four to twelve years. "We have reason neither to boast nor to be ashamed of what we have thus far accomplished, and we may begin this new era in the hope and belief that to us applies the bright side of the maxim of Cousins, 'It is better to have a future than a past.'"

As long as it is possible to secure such enthusiastic, successful teachers as Gross, Flint, and Delamater, the didactic lecture will occupy a place—probably a minor one—in the curriculum of medical study in our medical colleges.

At this transitional period in the history of medical education, there is a place for the spring and summer medical school, such as only the Medical Department of Wooster University and one or two similar schools now fill. Many medical students have found their study in the preceptor's office unsatisfactory. The usual medical course of five or six months has left him no means of pursuing his medical studies except in a sort of desultory reading, such as he may be able to do at home. Whether the spring and summer school has come to stay, and thus solve the problem of increased length of college year, or whether it is only a stepping-stone to a full year's course of medical instruction, I cannot say.

Among the many changes wrought in the requirements of a medical education, is that of not making a written "thesis" a requisition of graduation. When the only method of instruction was the didactic lecture, and the only examination an oral one, the faculty had no adequate means of estimating the fitness of a candidate to receive a medical degree.

The "thesis" gave some clue as to the applicant's knowledge of English grammar and orthography. It also, if honestly written, gave an opportunity to judge of many other qualifications of the student. But as the theses were written merely as a formality necessary to graduation, they deserved the just criticism of Dr. Gross, who said that "not one in fifty affords the slightest evidence of competency, proficiency or ability in the candidate for graduation." This being true, and written examinations having been substituted for oral ones, it is very easily understood how the "thesis" should fall into disrepute; yet I think the colleges are making a great mistake in giving up this important requisite of graduation. If the "theses" were printed, as in European schools, the strictures of Dr. Gross would not prove true. Then, there would be every inducement for the student to do his best. There would not be much danger of deliberate plagiarism when he knew that his friends, medical men, the public and the press would be his critics, instead of one professor, who, in all probability, would not read it. The publication of the "thesis" in this manner would have "a permanent historical value; they would reflect the character of the teaching, and would serve to stimulate the student to make original research."

Before medical journals were established, a number of valuable "theses" were published in this country. At that time it was permissible for a professor to "prefix a statement, not to exceed sixteen pages, as an introductory notice to a 'thesis' of a student." It was not necessary that the introduction should have any connection with the one discussed in the student's paper. Sometimes the professor would continue his subject through twenty or thirty dissertations, so that many of them are not wholly preserved. This is one of the few ways in which a physician of that time could make a record of his observations. "If a country doctor wished to make a communication to his professional brothers in those days, he was obliged to print it in pamphlet form at his own expense, or else send it to someone connected with either a medical school or with some scientific society, and trust to his making it known for him." This was the day of big books, and if a physician did not wish to write a volume, there was little inducement for him to attempt literary work.

"Boerhaave, one of the most remarkable physicians of the eighteenth century, and one of the most voluminous contributors to the medical literature of that period, left an elegantly bound volume at the time of his death, which stated on its title-page that it contained all the secrets of medicine which a physician need know. Upon opening the book it was found that all the pages were blank except one, which contained this sentence: 'Keep the head cool, the feet warm, and the bowels open.'" You will find before you complete your medical studies that there are *more* secrets for the physician of the nineteenth century to learn than were contained in this legacy of Boerhaave.

Now I presume, to be in fashion, I should put on a long face, and in a deep and sepulchral voice inform you that you have made a grave mistake in commencing the study of medicine; that the profession is overcrowded; that actual starvation stares you in the face; that it were better not to have been born. This is all nonsense. There are worse professions than the medical. It is true there are many unpleasant experiences in a doctor's life, but the same is true of every occupation. It is also true that barely half of you will follow the practice of medicine as a profession. Some of you will become lawyers, others preachers, others missionaries, others newspaper men, and many of you will enter mercantile pursuits. But what if you do? What have you lost? The knowledge you gain in the medical school is the most valuable you can have. It was Dr. Dick who said, "It is somewhat unaccountable, and not a little inconsistent, that while we direct the student to look abroad over the surface of the earth, and survey its mountains, rivers, seas, and continents, and

guide their views to the region of the firmament, where they may contemplate the moons of Jupiter, the rings of Saturn, and thousands of luminaries placed at immeasurable distances, and yet we should never teach them to look *into themselves*, to consider their own corporeal structure, the numerous parts of which they are composed, the admirable functions they perform, the wisdom and goodness displayed in their mechanism, and the lessons of practical instruction which may be derived from such contemplations."

Agesilaus, king of Sparta, when asked what things boys should learn, replied, "Those which they will *practise* when they become men." If this was good advice given to the youth who dwelt upon the shores of the Ægean sea, two thousand years ago, it is even more so, still, to the young men who dwell in this fairer land of ours.

It is remarkable what a beneficial influence a medical education has in strengthening the physical, mental and moral stamina of a young man. I think the young men who commence the study of medicine are not above the average in these attributes. In fact, if we are to believe the recent statements which have been made as to the preliminary attainments of medical students, they are quite the opposite. Yet I think no one will question the statement that the members of the medical profession are the peers of those of any other. They have a keener perception of the fitness of things. They may not have a great veneration for religious dogmas, but they have an acute sense of right and wrong. There is a subtle something that lends dignity and strength to the character of those educated in medical colleges, not found elsewhere. In just what this consists, I am not able to say. Those of you who, after completing your medical education, enter upon other pursuits of life, will never have occasion to regret the time and money spent in the medical school. The knowledge gained *about yourself* will prove ample reward. There are in every community a number of successful business men, who have been regularly educated in medical schools. I have never met one who regretted the time spent in medical study. I have met some who did the time spent in medical *practice*.

Those of you who are destined to become the physicians and surgeons of the future, are on the dawn of one of the brightest periods in the history of medicine. You will have the pleasure of reading some of the most wonderful books ever written. None of them have been completed. One of the most interesting will be on the subject of bacteriology. Only the first few pages of the introductory chapters have been written. It remains for you to write the book itself and tell us what influence these germs have upon the economy. Are they the cause of disease or only the result? One of the works, even more important than that on bacteriology, is that on ptomaines. Of this great book even the introduction is not written—only a few detached lines here and there, and these in foreign tongues.

There have been many additions to the ponderous volume on therapeutics. It is wonderful to think what has been done in the past five years, ever since some of you commenced the study of medicine. Cocaine has revolutionised the practice of eye surgery and diseases. New antipyretics have been introduced in such numbers that we are left all at sea as to which to use in the treatment of fevers. Acetanilide, and other similar preparations promise to supersede the use of opiates in the treatment of painful affections. Time forbids me to more than mention the advances of modern surgery. This book is much nearer completion than those in other departments of medical progress. The introduction to this work is complete, and many chapters written, yet there is much for you to do. The greatest book of all is barely commenced, and that is the one on "Preventive Medicine." It may be there are young men before me now, destined to make discoveries rivaling that of vaccination.

Who among you will discover some certain means of preventing the ravages of consumption, diphtheria, scarlatina, measles, typhoid or yellow fever? He who does will have his name placed alongside of that of the immortal Jenner, and will be remembered when that of Alexander the Great and Napoleon are forgotton.

If, then, you are about to lay the foundation of a professional life with such boundless possibilities, make them broad and deep, and it may be your good fortune to add a few pages to these wonderful volumes that will serve to add to the happiness of the race.

Whatever niche you may occupy, always remember that yours is a good and noble profession, and never permit yourself to degrade it to a trade.

The medical profession is the best profession; the worst trade. As a profession, the physician attends medical societies; he establishes medical schools; he publishes medical journals and books. As a trade, he publishes quack advertisements in the religious newspapers; he compounds secret nostrums; he promises no *pay*, no *cure*. As a profession, he attends sanitary conventions; he spends his best time and money in discovering the cause and the best means of preventing disease. As a trade, he magnifies small ailments; he caters to the ignorance, prejudices and superstitions of the people, and charges big fees for curing diseases which have no existence except in his fertile imagination. As a profession, he educates the medical student; he communicates to him all the knowledge which years of study, investigation and experience have taught him, so that the young man may practise intelligently and well; he endeavours, by every legitimate means, to elevate the standard of medical education. As a trade, he obstructs medical progress; he retards beneficial medical legislation; he cares not for the good of the people; no scheme so foul, no practice so low, but that he will undertake it to fill his pocket with money; he will violate every sacred bond of humanity; he will transgress every law of the land; he will sin against himself, his patient, and high heaven for a few paltry dollars. As a profession, when the physician makes a valuable discovery, he hastens to publish it in the medical journals, or announce it to the medical societies, where it will do the people most good and himself the most harm financially. If he invents a new instrument, instead of patenting and making a fortune out of it, he straightway puts it into the hands of the profession, without money and without price. He is animated by the same professional spirit when he meets a case of diphtheria, typhoid fever, or other preventable disease; he spares no time or labour to remove it, and thus lessons his already meagre income. Instead of one case of typhoid he might have had a dozen.

It is ever thus, the physician is constantly labouring to prevent those diseases he is paid to cure. He educates young men to enter the profession only to take the practice he has so laboriously established. Judged by any trade standard, the members of the medical profession are either fools or madmen! But let us thank God that the practice

of medicine is not a trade, but a grand, good and noble profession, of which it has been said, "it is the flower of our civilization, and when that stage of man is done with, and only wondered at in history, he will be thought to have shared as little as any in the defects of the period, and exhibited most notably the virtue of the race. Generosity he had such as is only possible to those who practise an art, never to those who drive a trade."

TUMOURS OF THE FEMALE BREAST, WITH NOTES OF CASES OF FOUR DIFFERENT TYPES OF THE DISEASE.

By Herbert Collier, M.D., L.R.C.P., M.R.C.S.,
surgeon royal naval artillery volunteers.

Tumours of the female breast are so common, and so interesting, both from a pathological and clinical aspect, that I shall make no apology for bringing the subject under the notice of the profession. And I have been particularly induced to do so, from the fact that some time back I had no less than four different varieties of this disease under treatment at one and the same time. These four cases included, a scirrhus in an early stage, and a rapidly-growing sarcoma of a most malignant type, which grew to the size of an adult head, burst in several places, giving rise to fearful hæmorrhages, and destroyed its victim (worn out by hectic and exhaustion) eighteen weeks from the first notice of anything amiss.

Although I shall not give this latter case in detail, I may be permitted to mention that the patient enjoyed the advantage of several of the leading opinions of this town, and although strongly persuaded at an early stage of her disease, and by myself subsequently (but before the growth took on such malignanty) to have it removed, she refused to allow any operative interference, and thus sank a victim to her own obstinacy.

In making the foregoing remark, I am fully sensible that many authorities theoretically condemn surgical interference in such acute malignant growths. But with all due respect to such opinions, I must submit that surgical interference is more justifiable, nay, imperative, in such cases, than in any form of disease of the breast. For if the surgical hand is withheld, and the patient is permitted to take her chance, what has she to look forward to? The few short days of her life (and in these cases they must be few and must be short) will be spent in exquisite agony of body, or in that exquisite agony of mind which will certainly accrue from apprehension of such suffering; in terror of frightful and ever to be dreaded hæmorrhages, or dazed and drunk from the effect of some anodyne.

On the other hand, there is little to be feared from the immediate effects of the operation, and it is a well-known fact that secondary growths in internal organs, should they occur, are less tyrannical in the suffering they inflict than the parent disease. And not only this, but removal of the offending disease affords immunity from immediate suffering, and gives fair chance of prolonging life.

My third case was particularly interesting, as it afforded some scope for diagnostic exercise. The patient was a married woman, æt. forty. Had never become a mother, or even pregnant so far as she knew, although she had been a wife since the age of twenty. Menstruation regular and natural. Family history good, with nothing of interest, or bearing upon the case attached to it. Parents alive, and enjoying excellent health: father, seventy; mother, sixty-four. First noticed a knot in the right breast about three months before I saw her. At this time it was not painful, but it afterwards became rather tender. Had increased to double the size during the last few months of its growth. When first seen by me, the woman, although spare, appeared in excellent general health, but somewhat nervous as to the nature of her disease. The left breast was found to be slightly wasted, but otherwise natural. The right breast larger than the left, presenting midway between the nipple and axillary border a hard, more or less globular, and circumscribed movable tumour, as large as a pigeon's egg; non-adherent to skin, nipple natural. Some tenderness produced on superficial pressure.

Looking at the woman's age, and to the fact that she asserted, "she had wasted a good deal since the lump appeared," together with the hardness and presence of an enlarged gland in the axilla, one could not help for the moment suspecting the presence of scirrhus. On more careful examination, however, doubt was thrown upon this conclusion by the mobility of the tumour, its non-attachment to surrounding structures (the skin could be freely moved over it), the healthy condition of the nipple, and the absence of that stony hardness so characteristic of this disease. A certain elasticity about it, with a slight sense of fluctuation, induced me to conclude that it might be a sero-(uno) cystic formation; and a grooved needle having been introduced, doubt was speedily effaced by the ready escape of some thin, clear serous fluid.

The treatment consisted in tapping, by means of a small trocar and canula, evacuating the contents of the tumour (which was of the same nature as the fluid just described, and which proved to be non-albuminous), and injecting half a drachm of pure carbolic acid by means of the canula, evacuating all the acid which would make its escape, and applying pad and compress. A good deal of pain followed this procedure, but only for a few hours, and although very little irritation followed, sufficient inflammation ensued to effect adhesion of the opposite surfaces of the sac. Since the operation, performed now many months ago, the patient has never had the least return of her local trouble, and the breast to all appearances is perfectly healthy.

My fourth and last case I will ask permission to give at greater length.

Mrs. D——, a married woman, æt. twenty-nine; mother of four children, of which three are living (one having died in infancy of bronchitis); consulted me concerning a painful lump in her left breast.

Family History.—Father died at the age of thirty-six, of heart disease and dropsy. Mother, sixty-five; healthy, with the exception of a weak heart, which gives rise to occasional attacks of dyspnœa, for which she was then under my treatment. Eleven aunts: one died of consumption. The rest are healthy. Four uncles: one died of typhoid fever, and one lost at sea, the remaining two being alive and healthy. One brother and one sister, both alive and healthy.

Previous Condition.—Had chicken-pox at an early age, and was subject to attacks of bilious headaches; otherwise always enjoyed excellent health. Menstruation regular (occurring at intervals of three weeks), and accompanied by no pain or constitutional disturbance. Has always had good times at her confinements.

History of Present Disease.—About three years previously after the death of the child already alluded to, and whilst

pregnant, she became subject to attacks of intense pain in the region of the left breast, which was also very tender. Did not notice any alteration in the size or shape of the gland. These symptoms continued during her whole pregnancy, and after the birth of the child. At this time it was found that the glands secreted scarcely any milk, and the pain continued as before. Eight months ago, when weaning her child, the pain became still more frequent, and she now noticed for the first time a small hard lump situated at the outer side, about two inches from the nipple. This was at first painless on pressure, but subsequently became extremely tender. Together with the steady increase in the size of lump, the pains have become more constant and of greater severity.

An interesting feature in this history is that the patient declares that during menstruation (which lasted eight days) the pains entirely ceased, and the lump became distinctly smaller, and less tender. This fact I subsequently verified for myself.

Condition.—At the time of first seeing her the patient was a florid young woman, of clear skin and healthy appearance, although somewhat spare, and conveys an anxious expression of countenance. General state satisfactory. All the organs healthy. The right breast natural, left breast small and wasted, and presenting to the outer side of the nipple, and about two inches from it, a smooth oval elastic tumour, the size of a bantam's egg, apparently incorporated in the gland substance, not fixed to surrounding structures, skin, and nipple; perfectly healthy.

Having diagnosed a simple adenocele (synonymous with the chronic mammary tumour of Sir Astley Cooper, mammary granular tumour of Paget, or adenoma of Birket), and since numerous ingenious and equally painful forms of counter-irritation (from the production of mere hyperæmia to ulceration of the skin) had been attempted without success, and iodide of potassium and iodide of mercury had been tried without producing any beneficial effect, I strongly advised the patient, on account of the constant pain, and constitutional disturbance to which it was giving rise, to have it removed. This she gladly consented to, and the operation was effected, whilst the patient was under chloroform, on the 20th January. Listerism was observed, as carefully as the absence of a spray would admit. The vessels were twisted, and a drainage-tube having been inserted, the edges of the wound were brought together by six interrupted silver sutures. The temperature never rose above 99°, and that only on the second night. The wound united by first intention throughout its entire length, except where the ends of the drainage-tube emerged. There was absolutely no formation of pus, except at these two points, and the patient at her own special request was permitted to leave her bed on the fifth day. From this time she made an uninterrupted recovery.

AN ENQUIRY INTO THE CURRENT THEORIES OF THE CAUSES AND NATURE OF ACUTE RHEUMATISM, AND THE TREATMENT GENERALLY ADOPTED FOR ITS CURE.

By Alexander Harkin, M.D., F.R.C.S.,

CONSULTING PHYSICIAN, MATER INFIRMORUM HOSPITAL, BELFAST.

(*Continued from page* 145.)

I HAVE already recorded my opinion that the proximate or exciting cause of acute rheumatism is a chill, and that the morbid effect is produced through the agency of the nervous system; that it is essentially a specific form of endocarditis; and that the cardiac affection is not merely an incident or occasional complication, but in reality the initial or seminal principle from which spring up the myocardiac, arthritic, pericardiac, pleuritic, meningeal, and other occasional developments and complications of the disease. I believe that endocardial inflammation is always present in acute rheumatism, but not always recognised, and not always recognisable in its early stages, but that in such cases its presence is always to be presumed and taken into account, and provided for by appropriate treatment. The clinical history of endocarditis, in its relation with acute rheumatism, is both interesting and instructive; its *rôle*, as the chief factor in its production, was only established slowly and step by step, just as the discovery of the circulation of the blood was the work of centuries, and not of one but of many minds, having been foreshadowed by Galen, by Vesalius, by Sylvius, by Fabricius, and Servetus, until the genius of Harvey, building on the firm basis of previous discovery, completed the edifice in a perfect manner. It was thus that Sydenham, about the end of the 17th century, whose practice was founded on the obvious indications of nature rather than on prevalent theories, was the first to clearly distinguish acute rheumatism from gout, to which he was himself a martyr; and to mark his estimate of its inflammatory nature, he treated it by antiphlogistics and free bleeding. The next important advance in diagnosis was not made till the beginning of the 19th century, when Dr. P. M. Latham, in 1826, imparted to his class in St. Bartholomew's Hospital the discovery of a new clinical fact; that whenever the heart was affected in acute rheumatism, a sound, different from the sounds of health, always accompanied its contraction; this was the bellows systolic murmur, but its significance was then unknown to him. It remained for Bouilland, in 1835, to reveal to the world that this abnormal sound was caused by inflammation of the endocardium, the truth of which he had abundantly verified by the *post-mortem* examination of patients dying in hospital from rheumatic fever. About the same time, Dr. Watson and Dr. Stokes, as the result of independent observations, assigned to the exocardial murmurs their distinctive diagnostic value, as the certain signs of pericardial inflammation. Dr. P. M. Latham, whose writings I shall frequently have to quote, and who was gifted with a keen perception of scientific truth, accepted the teaching of Bouilland, confessing that "Endocarditis, at present chiefly known as a concomitant of acute rheumatism, was unknown to him in its real extent and frequency during two-thirds of his professional life."

This recognition of the concomitance of endocarditis and acute rheumatism, led on by natural development to the final pronouncement of Hueter, who regards endocarditis neither as a complication nor a mere concomitance, but as the primary pathogenic factor in its production.

This thesis, so much opposed to the humoral pathology, may not prove quite acceptable to those theorists who, on finding the blood altered in composition by the endocardial inflammation, as in pleuritis or pneumonia, attribute the deposits on the lining membrane of the heart and the joints to a hyperinotic state of the blood, instead of crediting the change to the agency of acute inflammation of these organs, and who endeavour, by alkaline and other drugs, to alter its chemical and vital character. John Simon, now Sir John Simon, writing many years after these demonstrations and discoveries, and treating of acute rheumatism as "a disease

of intense over-fibrination of the blood, and one in which there are other conditions besides *quantity*, making the fibrine easy of precipitation," writes: "I believe that the origin of these vegetations is directly humoral; that they arise as fibrinous precipitations from an overcharged solution, the valves encrusting themselves with fibrine just as a stick in certain streams coats itself with a calcareous envelope." While, *per contra*, Sir William Gull, the advocate of solidism and the localisation of disease, treating of gout, rheumatoid arthritis, and rheumatism, writes thus: "Whether they have humoral sources has of late become more and more doubtful; of the pathology of acute rheumatism we may be said to know but little beyond its clinical records and its symptoms, but, unhappily, this has not always been sufficiently recognised, and too often a dangerous polypharmacy has rushed in to the cure where science has not yet advanced her foot." It is most probable, however, that the endocardial theory of acute rheumatism, like other great truths, will in course of time gain the mastery over prejudice and long-cherished predilections.

The testimony of medical authorities on this etiological point, varies according to their scientific training and modes of clinical examination; those, who like Bouilland and his cotemporaries, recognised or mistook the products of endocardiac inflammation for its signs or symptoms, taught that one half, others that three-fourths of rheumatic patients suffered from endocarditis; later writers have gradually increased the percentage, until but a small proportion remains in which their instruments of precision cannot recognise either its active presence or its morbid products. Thus, of 136 inmates of St. Bartholomews Hospital, from 1836 to 1840 inclusive, under the care of Dr. P. M. Latham, the subjects of acute rheumatic, the doctor states, "that three-fourths were affected with endocarditis, while a large portion of the remainder were saved from its infliction, by active anticipative treatment, adopted as soon as the premonitory signs: such as anxiety, tumultuous action of the heart, the lengthening and roughening of the first sound or præcordial pain, had appeared and given warning of its approach." Dr. Sidney Coupland, in the debate at the Royal Society, as already quoted, declared "that of his eighty-four cases there were only twenty out of the whole in which endocardial bruits were not detected at one time or another." While Dr. Sibson testified that out of seventy-four cases of acute rheumatism, treated in St. Mary's Hospital, only one-fifth escaped from endocardial inflammation. If necessary, many other reliable authorities, bearing similar testimony, might be referred to; but, outside the statistical argument, the literature of the subject strongly upholds the theory of the concomitance, and the omnipresence of this potential causative agent in acute rheumatism. Hueter, according to Sonator, asserts "that endocarditis may be present without giving rise to either subjective or objective symptoms; that it may well precede the inflammation of the joints, even although not recognised till afterwards; that its presence must be assumed in those cases which appear to run their course without any cardiac complication." Dr. Stokes in his work upon "Diseases of the Heart and Aorta," p. 103, writes "that cardiac inflammation may be developed, unattended by any evidence of valvular disease, and that he has seen cases that could not be explained on any other hypothesis, except that of the absence of murmur in endocarditis." The influence of this disturbing element affords an explanation of the difficulty put forward by Aitken as to "why the rheumatic inflammation of the joints is frequently preceded by febrile disturbance, and also why sometimes, the fever runs so high before any local symptoms have established themselves."

That rheumatic fever may exist without any joint affection, did not escape the observant mind of Dr. Graves, the great clinical teacher of this century; he announces the fact in his "Clinical Lectures on the Practice of Medicine," first published in 1843, and supports his statement by giving the particulars of a case in which the fever continued, after all joint disease had disappeared. After relating the leading symptoms, he observes, "Here we have a man admitted with rheumatic fever and inflammation of the joints; we try to cure the disease, and we succeed in removing the fever, but the joints remain inflamed; we remove this also, and congratulate ourselves on a recovery, and we again have fever and arthritic inflammation; we overcome this, and again a relapse comes on; but mark the difference, we have now fever, but the joints are unaffected! This is a curious circumstance, and confirms me in an opinion I have entertained for some time, that we may have rheumatic fever without inflammation of the joints. Again he says, "these peculiarities I have frequently remarked, but it was only lately that I became aware that this species of fever may exist without inflammation of the joints. These considerations are of practical interest, and prove that in the treatment of acute rheumatism, we cannot hope to cure the fever by means which merely tend to get rid of the arthritic inflammation. *As arthritis may exist without rheumatic fever, so rheumatic fever may exist without arthritis; when combined, they each aggravate the other, but the cure or disappearance of one, does not necessarily determine the removal of the other.*" Like Dr. P. M. Latham, he teaches "that in rheumatism the action of the heart must be carefully watched, and when it becomes increased without any apparent cause, that occurrence alone is sufficient to warn us of the approaching danger. This point has not, I believe, attracted the attention it deserves, and its importance is enhanced by the fact that an increase of the heart's action may not only precede the physical but the constitutional symptoms of that organ or its membranes, and consequently be the only beacon to forewarn us of a danger still beyond the visible horizon, and undiscernible by any other means." Bouilland, to whom the pathology of acute rheumatism owes so much, points out that in this disease, endocardial inflammation may exist in different degrees of intensity, and that its presence may often escape the investigations of the unskilful physician. He also objects, with Graves, to the vulgar belief of the prevalence of metastasis, and refers to the persistence of the fever in many rheumatic patients, even after the joint disease had disappeared, a fact only explicable by the persistence of the cardiac affection. He also alludes to the fact that pain is not essential to rheumatism. The existence of acute rheumatism or rheumatic endocarditis in children, without any arthritic concomitance is a matter of common observation, these cases are often accompanied by erythema nodosum, on the extremities and trunk, or by well-developed nodules on the skin and fibroid structure, as much indicative of rheumatic origin as arthritis itself, and too often leaving behind them a heritage of valvular disease, chorea and other nervous affections. The important observations of Dr. Thos. Barlow and Dr. J. Warner on subcutaneous nodules in children, subjects of acute rheumatism and chorea, founded on the history of twenty-seven cases, demonstrate

clearly that they truly conform to the general type of acute rheumatism, and that they may be considered in themselves as pathognomic of rheumatism, even in the absence of pain; when, as is so often the case in childhood, the evidence of well-marked arthritis may be wanting, and that their nature is probably homologus with that of the inflammatory exudations and vegetations on the cardiac valves after death from acute rheumatism. Some cases, published by Dr. Gee in the 24th volume of St. Bartholomew's Hospital Reports, although not altogether very well marked examples, support, to a great extent, the teaching and the experience on this point, of our bygone masters in pathology.

That the great pioneers in rheumatic pathology regarded the disease not as a fever, but as an inflammation, may fairly be deduced from their treatment of the affection; and the modern preference of the term "acute rheumatism" to that of "rheumatic fever" is an involuntary admission of its truth. The broad distinction which Andral drew between fever and inflammation seemed to be also known and recognised by them, and to have powerfully influenced their treatment. To begin with, Sydenham, perhaps the greatest of English physicians, relied principally upon the abstraction of blood for its removal.[1] In his own nervous words, he directs "Ut primum accessor, statim sanguinis ℥x. e brachio *Lateris Affecti*, mitte jubeo. . . . Die sequenti, sanguinis tantumdem detrahi principio; atque intercalato die uno alterove, pro ægri viribus, tertio; dein interjecto trium quatuorve dierum intervallo (prout ægri vires ætas constitutio aliæque circumstantiæ suadent monentque quarto, atque ultimo ut plurimum, venesection repeto, raro enim usu venit, ut ultra quartam vicem venam incidamus, nisi vel regimen justo calidius præcessent vel medicamina calidiosa ægro præter necessitatem fuerint ingesta."

And Bouilland, with his practical knowledge of the pathological connexion between endocarditis and acute rheumatism, differed but slightly from Sydenham in the persevering manner in which he prescribed venesection, *coup sur coup*, as he expressed it, often to the extent of four to five pounds and more. Recognising, apparently, the *rôle* of the nervous system, Bouilland also prescribed opium for the relief of pain, and as adjuvants, blisters, compression, bandages, spread with mercurial ointment, and strict antiphlogistic regimen, till resolution was accomplished.[2]

Dr. P. M. Latham, whose classic work on "Diseases of the Heart" is practically a dissertation upon the cardiac affections allied with acute rheumatism, shows, in his treatment of that disorder, to what pathological school he has given his adhesion. With Sydenham and Bouilland, he regards it as one of the phlegmasial, and treats it as they did, by depletion, by opium, and by purgatives. In his treatise, the pathological alliance between the nervous and vascular systems in the causation and treatment of rheumatism were fully recognised, and their recognition was practically exemplified in his plan of treatment. For, while he condemns those that rely solely on blood-letting, he disapproves as much of the treatment by opium alone, the soothing remedy of that day, so much relied on by Corrigan and others; and while chiefly depending on judicious and moderate bleeding and purgation, he does not discard the aid which opium yields in the alleviation of pain, and its sedative influence on the nervous system. His efforts were not merely directed to the prevention of death in acute rheumatism; he aimed at curing the disease by the restoration of the endocardium to its normal condition, and thus not alone saving the patient from impending death, but preserving him from permanent cardiac injury and its painful consequences.

As a proof of Latham's conviction that endocarditis and acute rheumatism were of homogeneous nature, he prescribes for each an identical treatment. What he orders for acute rheumatism he repeats when prescribing for the cure of endocarditis. "Bleeding, mercury, opium—the very remedies you used in acute rheumatism are, I say, still your main reliance when inflammation attacks the heart; but bleeding by leeches or cupping, after or exclusive of venesection, opium to calm the nervous system, and to give effect to the operation of mercury (calomel), is our mode of administering it. Latham, however, in every case of acute rheumatism seen early, devoted all his energies to forestalling the development of endocarditic inflammation, and he repudiates, in forcible terms, the conduct of those who, in such cases, prefer to wait for the auscultatory signs, and thus be absolutely assured of its active presence. "You would not sacrifice men's lives," he says, "to the vanity of diagnosis. The auscultatory signs, when they come, will only serve to localize the disease; the nature is plain enough already, and we treat its nature, not its seat."

And the depletive and antiphlogistic plan of treatment continued to be the favourite mode until very lately. Dr. Law of Dublin, writing in 1864, treating of venesection in acute rheumatism says: "We still employ it, and we conceive we do so beneficially, although not to the same extent as we once did." His treatment was venesection once, very seldom twice, followed by the exhibition of colchicum Abercrombie, by blood-letting, antimony, and opium; and Begbie, by lessening the amount of circulating fluid, and thus altering its constitution; but within little more than a decade, the teaching and experience of eminent pathologists and physicians has been ignored, and the majority of medical practitioners have succumbed to the attractions of a blind empiricism.

My own peculiar plan of treatment, which may be called the abortive plan, proceeds to a great extent on similar lines as those great authorities I have referred to. Recognising the disease as one originating in cardiac inflammation, my aim has been to subdue it by counter-irritation and depletion before the development of the inflammation has lapsed into organic change. Latham says, "if experience has found any treatment which is preventive of endocarditis or pericarditis, then is the time for carrying it into effect—the time of the heart's immunity, which would thus become the most eventful and most important period of the disease." And this treatment, eminently successful in the early stage of acute rheumatism, is also very effective, even after evidence of valvulen disorder. My treatment is of the simplest kind; the application of a blister, four by three inches, for eight hours to the cardiac region, followed immediately by cotton wool dressing, preceded, if in plethoric patients, by leeches in the pericardial region, or cupping at the back in the space between the inferior angle of the scapula and the spinal

[1] The real distinction between inflammation and fever is found by M. Andral in the constituents of the blood. In inflammation its fibrine is always in excess; in fever, never. Thus, acute rheumatism is preeminently an inflammation, and is taken altogether out of the category of fevers.—*Hæmotologie Pathologique*. Quoted by Latham (Lecture xi., p. 222, "Disease of the Heart").

[2] "Nouvelles Recherches sur le Rheumatism Aigue en General et Specialement, etc." Par J. Bouilland, Professeur de Cliniques Medicale à la Faculte d'Medicine, Paris, 1835.

column; but bleeding is the exception, and this remedy often succeeds in removing all the special symptoms, whether subjective or objective, in the space of twenty-four or forty-eight hours.

I scarcely ever prescribe medicine of any kind, but should the case be prolonged, I do not object to the use of opium, alkalies, or salicin, but I relegate them to their proper place, as adjuvants or handmaids in the treatment, after the cardiac safety has been assured through the use of appropriate remedies. I do not mean to convey that by the use of this topical remedy I have succeeded in every case, or that it is entitled to the designation of a specific. I am cognisant of several failures in my own and in the practice of others; I have not always been able to abort the attack, when accompanied with skin disease, such as peliosis rheumatica, pemphigus, erythema multiform, or the sequel of pregnancy, or when engrafted upon chronic valvular injury; but when successful, as it generally is, it effects a perfect cure, a complete recovery, for such an occasion as a single relapse is unknown in its history. I certainly have had three well marked cases of a recurrence of the disease after complete convalescence, due to fresh exposure to cold and moisture, but no relapse while under treatment or without evident cause. According to Latham, "perfect cure does not contemplate that after their removal diseases shall never return; but it does contemplate that before they can begin to return, their actuating cause will have to begin also." I believe with Cullen that "remedies cure disease, only in so far as they remove their proximate causes."[1] If then, Cullen's dictum be accepted, and if a blister over the region of the heart cures a case of acute rheumatism, and its articular complication, it surely would not be unsafe to infer that the proximate cause itself is located in the same region, the heart.

As to the *rationale*, it appears to me that the blister effects the cure by its acting as a depletive, a counter-irritant, a revulsive, and derivative. By the drain which it establishes several ounces of the liquor sanguinis, the serum and albumen of the blood are thereby removed from the circulation in the immediate neighbourhood of the inflamed organ; by its sedative influence upon the nervous system, whose excitability is increased in proportion to the extent of the inflammation, it accomplishes its purpose by lessening the force of the current of blood, and, diminishing its rapidity, it has all the advantages without the disadvantages of venesection, and thus induces a condition most favourable to the resolution of the disease. In discussing the influence of remedies upon the heart, and their incidental effect upon concurrent diseases, the *modus operandi* of drugs administered for the cure of rheumatic fever cannot be passed over. Thus, when the salicylates relieve temporarily, or produce symptoms of poisoning, it is solely through their action as heart-depressants. The potash salts, in like manner, require the fortifying influence of quinine to preserve the heart from their paralysing effects; colchicum, veratrum viride, veratria, all act upon the cardiac and arterial system. While opium acts on the nervous system, and in sleep produces anæmia of the brain, it depresses the functional activity of the cerebral cells; it powerfully influences the circulation and the heart by its action upon the inhibitory cardiac centre, and the intra-cardiac ganglia; and in all acute inflammations it is our chief reliance. Antimony and mercury are depressants and antiphlogistics, and even quinine in large doses produces weakness of the heart and paralysis of the vaso-motor centre; in excessive doses it causes rigor mortis and contraction of the cardiac muscle; and so with all those remedies for acute rheumatism it is found that if at all effective, it is only as heart-depressants and antiphlogistics that they operate, and not through any occult therapeutic agency, and that the measure of their beneficial influence in the relief of individual symptoms of that disorder is exactly the extent to which they operate directly or through the medium of the nervous system on the heart itself.

I shall now proceed to relate the particulars of a number of cases, as observed by myself and others, in which by a simple remedy, and practically without the administration of any medicine, the cure effected was at once rapid and complete. Some of these cases appeared in the "Transactions of the Ulster Medical Society," others in America, and at various dates since my first case, which I now give as it arose.

Case 1.—On October 24th, 1879, I visited Constable H., R. J. C——, æt. thirty, married. He had suffered from a rigor three days previously, followed by pains, especially in the left knee and thigh, which were red and swollen. 25th. Pain had extended to right knee, both ankles and shoulders. 26th.—Left elbow also engaged; perspiration acid and profuse; urine scanty, and loaded with urates. 27th.—State unchanged. Ordered an opiate at bed-time. He had been previously laid between blankets, and his joints wrapped in flannel and cotton wool. 28th.—Had not slept for a week; at one p.m., temperature 102°; pulse 108; no improvement, no cardiac affection observable; at that hour I applied a blister, four by three inches, over the region of the heart, ordering its removal in eight hours, and to be replaced by cotton wool. 29th.—Noon: found the patient completely relieved; countenance cheerful; pulse 90; temperature 98°; tongue clean; thirst diminished; perspiration gone; urine copious and clean; and from being on the previous day paralysed in every joint and quite helpless, he was able without pain to flex and extend every joint, and to sit up in bed with ease. He stated that he began to feel relief at six p.m. on the previous day, just five hours after the application of the blister. Soon after that he fell asleep, and that having occasion to rise during the night he walked unaided across the room, and only remembered his rheumatism after returning to bed. On examining the joints, every trace of redness had gone, and the swelling was scarcely perceptible, the joints could be grasped firmly without pain. He then stood up and walked across the floor without any undue effort. 29th and 30th.—Still improving; pulse 90; temperature 98°; swelling and pain absolutely gone from every joint; heart free. November 1st.—Pulse 84; temperature normal; convalescence complete. A week after he walked to my residence on a frosty day without injury, and he soon after returned to duty.

Case 2.—*Subacute Rheumatism.*—On November 16th, 1879, visited Mrs. B——. She had been confined fourteen days previously; child at nurse; had a shivering on 11th; next day, both hands and left shoulder became painful and swollen; pain increased at night; sleepless for three preceding nights. I found both hands swollen and powerless; all the carpal, metacarpal, and carpo-phalangeal joints were implicated; perspiration profuse; urine scanty and high-coloured. This was her third attack; I did not prescribe a particle of medicine, but applied a blister over the cardiac region. Calling next day, I found the patient sitting up in

[1] Cullen's "Preface to Nosology," p. 16.

bed. Despite the pain of the blister she had slept all night. Perspiration had departed *puri passu* with the pain. The right hand had already regained its power; fingers quite free; and in three days the left hand which had been most swollen was quite relieved. I visited her but twice again. On the last occasion I found her down stairs nursing her baby, and perfectly able to take charge of it. My friend, Dr. William Aickin, saw this patient once with me.

Case 3.—*Acute Rheumatism.*—J. F. R——, æt. fourteen, tall and stout, had a rigor on April 6th, 1880, followed by pains in right and left knee, and ankles. Visited him on the 9th, and found him lying on his back, unable to move, from the swollen state of his joints, especially his elbows. Pulse 88; temperature 101°; urine clear, but scanty; perspiration plentiful. 10th.—Condition unchanged. 11th.—Still sleepless, although had an opiate on previous night; urine now highly acid, with copious deposit; heart pulsating violently; distinct systolic apex murmur. Dr. Whitla, who examined the patient this day, concurred in the diagnosis. In his presence I applied a blister, *regioni cerdis*, to be retained for eight hours. 12th.—We found the patient sitting up and relieved; he had slept soundly all night after the removal of the blister, and had got up unaided to the night-chair; urine again clear; pain and swelling reduced in all the joints, which he could flex without trouble. Pulse and temperature unchanged. 13th.—Still progressing; slept well; urine clear; sweating gone. We found him again sitting up, and anxious for removal into next room. Pulse 68; temperature 99°. 14th.—Temperature 98°; pulse 60. 16th.—Temperature normal; pulse 56. All traces of swelling had gone, and convalescence now complete. He had taken in all ten grains of opium. Dr. Whitla watched the progress of this case with me. The pulse and temperature in this case had fallen so low that I had to order stimulants. Fourteen days after all trace of cardiac symptoms had departed.

Case 4.—*Subacute Rheumatism.*—Miss L. V——, æt. ten, had a rigor on April 17th, 1880, followed by great muscular pains and general malaise, succeeded by urticaria. Both ankles then became painful, red, and swollen, as well as the right knee. I saw her upon the 19th, then in bed, and unable to move from the severity of the pains: pulse 88; temperature 101.0°; urine scanty; clear of acid reaction; bowels confined; perspiration very free; increased palpitation of the heart, and well-marked apex systolic murmur. Ordered a laxative. 19th.—Fever and thirst increased; had not slept. Applied a small blister over the cardiac region for four hours; the joints had been previously enveloped in cotton wool. 20th.—Pain and swelling of joints much less; had slept well; perspiration diminished; urine muddy, with pink deposit; tongue clean; soft murmur over apex. Pulse 86; temperature 100°. 21st.—Pain all gone: pulse 84; temperature 99°. Slept well. Appetite restored. 22nd.—Slight recrudescence of pain in right knee, which is stiff. 23rd.—Pain and swelling gone from knee: pulse 80; temperature normal; blister almost healed; much stronger. 24th.—Convalescent; to be removed to another room. The cardiac symptoms did not quite subside for a period of fourteen days.

Case 5.—*Acute Rheumatism.*—Visited A. S——, æt. thirteen years, on November 6th, 1880, an inmate of an industrial school, suffering from pain in every joint; her third attack. She attributed her illness to a long walk on November 1st, a very frosty day. She was removed to a newly-plaistered infirmary, where I found her with L. G——, the next case. Pulse 112; temperature 103°; heart beating tumultuously; systolic apex murmur. Fifteen minims of tinct. opii were given at bedtime. 7th.—Next day no improvement. 8th.—Before visiting I requested Dr. Esler to accompany me. Pulse was then 120; temperature 103°; face flushed, and she was crying loudly for something to cool her. I then applied a blister over the heart for six hours, to be dressed as usual with cotton wool. 9th.—Visited with Dr. Esler. Our report was pulse 118; temperature 102°; painful symptoms much abated; bruit softer; ankles free; shoulder better. Can flex knee freely. She walked across the room, and returned without difficulty. To-day friction to-and-fro sound first appeared. Applied a blister over the sternum. 10th.—Pulse 96; temperature 99°. Pain absent everywhere, except on left hip; urine clear; slept well. 11th.—Pain of hip gone; pulse 100; temperature 102°; pericardiac trouble subsiding, as well as apex murmur. 12th.—Dr. Whitla joined Esler and myself. His report was: "No affection of any joint whatever; nor is there pain or tenderness anywhere, except over the cardiac region. Pulse 90; temperature 101.5°. A loud friction murmur over the entire area, making a feeble endocardial murmur, near to the left nipple." 13th.—Pulse 86; temperature 99.5°. Cardiac sounds still loud; no articular trouble; further signs of effusion, with prominence of left side. 14th.—Area of dulness diminished: temperature 98°; pulse 72; friction sound less; bruit still perceptible; crepitation at base of lung and left axillary region. A mustard poultice to be applied. 15th.—Pulse 60; temperature 96°; countenance pale; extremities cold. To have two ounces of wine in the day, and hot water bottle to feet. 16th.—Pulse 72; temperature 97°; four ounces of wine. 17th.—Found her sitting up in bed at lunch: 18th.—Improved in every respect, and proceeding to convalescence, when an inexperienced nurse stripped her at the fireside, exposed her to the cold air of the room, and splashed her over with tepid water, when she immediately took a shivering, and all the cardiac symptoms returned with violence. A fresh blister, however, and a week's rest in bed served to restore her, and before the end of the month of November she was quite well, and free from all cardiac and articular troubles.

Case 6.—*Acute Rheumatism.*—L. G——, æt. fourteen; first attack; resembles Case 5 so much that it need not be pursued from day to day. Exposed to the same chill while out on November 1st; lay down about the same time; had similar cardiac ailments; and about the same time recovered her strength. She was then maltreated in the same way by exposure and douching in the newly-plaistered infirmary; took a fresh rigor again; had a return of the cardiac affection; but was not so fortunate as A. S——, for after getting over all acute symptoms, there still remains a persistent murmur at the apex. Both Drs. Whitla and Esler saw this case daily along with A. S——, as she was in the next bed to her. She was up and going about on December 4th, and in six months after undertook the duties of a domestic servant.

The next five cases are contributed by Dr. J. Walton Browne, Senior Surgeon, Belfast Royal Hospital.

Case 7.—*Subacute Rheumatism.*—Miss O. B——, æt. twenty-four, ill since February 10th, 1880, was seen by me on the 16th. She took ill with sore throat and general pains, especially in her knee-joints. She perspired freely on the

12th, and felt better. Her hands and wrists now became swollen and painful, so as to prevent sleep. The pains continued in all the joints, and she became quite helpless. When I visited her, both hands and wrists were much swollen, and she could not bear the slightest pressure; had pain in the præcordial region, with slight mitral murmur; pulse 120; temperature 103°; evidently suffering from acute rheumatism. I prescribed no medicine; but following out the treatment suggested to me by my friend, Dr. Harkin, I applied an emplastrum lyttæ, three by three inches, over the heart for twelve hours. On my next visit, sixteen hours after the application of the blister, I found all pain gone from the hands, except when she moved them, and from the other joints. All swelling had already subsided; the pulse had fallen to 88, and temperature to 99°. Next day I put her on a mixture of potass bicarb. and tinct. opii. She was then able to leave her room, and upon February 26th she left for the country. Certainly the effect of the blister in this case was marvellous, the pain ceasing, pulse and temperature coming down, and all swelling subsiding in sixteen hours after the application of the blister.

Case 8.—*Subacute Rheumatism.*—Miss A——, from the west of Ireland, was seen on February 14th, 1881. She complained of weak vision and general debility, and was very anæmic. I did not visit her again till March 19th, when I found her labouring under an attack of subacute rheumatism. Pulse numbered 20; temperature 99.4° The wrists, knees, and ankle-joints, were very tender to the touch. Ordered a blister, two by two inches, to be applied for twelve hours over the cardiac region, and cotton wool round the joints; milk diet. Called two days afterwards, and was surprised to find my patient sitting up, and all pains gone. She was very weak, but with treatment was quite well upon April 1st.

Case 9.—Miss M. S——, æt. four years, was seen by me upon March 6th, 1881. She was suffering from an inflamed throat, with glandular enlargement in the neck. I prescribed the routine treatment, and did not see her again till March 11th. When I visited her, I found her ill with acute rheumatism. The wrists and knee-joints were swollen and tender; pulse 120; skin perspiring. She had not slept on the previous night, on account of the excessive pain. Temperature not taken. Applied a blister, two by two inches, over the cardiac region for ten hours; cotton wool to the joints affected. No abnormal cardiac sound could be heard. Next day (March 12th) all pain was gone from the wrist and knee-joints. The child had slept for some hours after the blister was taken off; the pulse was down, the expression of the face calmer, and the patient seemed quite easy. On the 13th, I ordered her an alkaline mixture. On the 14th, she was out of bed, and in a few days was running about.

Case 10.—Martin M. S——, æt. five years, brother to previous patient, was visited on March 26th, 1881, suffering from swelling of wrist and knee-joints; pulse 120; thirst excessive; throat congested; had not slept for two days. His mother, knowing the value of the blister in the former case, suggested it to me. I ordered a blister, three by three inches, to the cardiac region for twelve hours, and cotton wool over the inflamed joints. March 27th.—Patient was seen by Dr. Harkin along with me. All tenderness of joints was gone, but some puffing still remained over the wrists; pulse 120. Patient complained of headache, and his pupils were dilated; he had also on the anterior surface of the abdomen and legs a number of spots, resembling purpura. Ordered some bromide of potass with the bicarbonate, and counter-irritation to the nape of the neck. 29th.—All pain and swelling of joints gone; can move hands and legs freely; pulse 100; taking food; still has an inflamed throat, for which I prescribed. April 3rd.—Patient quiet well, with the exception of being a little weak and anæmic.

Case 11.—D. C——, æt. twenty-two, was admitted into the Royal Hospital, Belfast, on March 1st, 1881, suffering from a lacerated wound of the little finger, left hand, followed by an attack of diffuse cellulitis of forearm and arm. After free incisions he became convalescent at the end of three weeks. He had been up but one day when he began to expectorate bloody mucus, and complained of a sore throat. His pharynx was congested and œdematous; this continued for three days, when his temperature suddenly rose to 102°, pulse to 120. He also complained of pain in left ankle-joint. Cotton wool and milk diet were ordered. Next day, left knee and elbow-joints were involved; temperature 103-4°; pulse 120. Great pain and acid perspirations were complained of. Dr. Harkin this day visited the patient by request. On examination of the heart, a mitral whiff was detected. Emplastrum lyttæ, three by three inches, was now applied over the cardiac region for ten hours. Upon its removal, the patient declared himself almost free from pain, although the joints were still swollen. The temperature, which on the application of the blister stood at 103-4°, came gradually down to 99° in forty-eight hours. The patient made a rapid recovery, and left the hospital three weeks from the commencement of the rheumatic attack.

I shall give the particulars of other cases out of my note-book, the types of many others cured since 1879, and then quote from the experience of others.

Case 12.—On December 26th, 1882, I was called to visit W. D——, æt. sixteen years, a mill worker; his second attack. His previous illness was in 1878, when he was confined to bed for eleven weeks, and was not able to return to work for ten weeks. He was attended by two Belfast medical men for that attack. He had a rigor on December 21st, and lay down on the 22nd. I found him lying on his back, sweating profusely, with pain in all his fingers, both wrists, elbows, and shoulders, which were red and swollen, both ankles, and both knees. His back was very painful, and he was incapable of moving off it. Urine scanty, and loaded with lithates. He had not slept for four nights, and had been delirious for the last two. At noon his temperature was 101.8°; pulse 88; heart beating tumultuously, with well-marked apex-systolic murmur. At that hour I applied a blister (six by four) below the left nipple, to be retained for eight hours, and dressed with cotton wool.

December 27th.—Found the patient much relieved. He had slept for four hours. Temperarure 100.8°; pulse 80. Urine unchanged, and red. Had regained some power of his arms and legs; sweating somewhat diminished; pain much less.

December 28th.—Slept nine hours. Pain now only present in left shoulder. All other joints free. Was able, with assistance, to sit up in bed. Back weak, but free from pain.

December 29th.—Temperature 99.4°; pulse 72. Urine plentiful and clear. Got up and sat an hour in an arm chair, having put on his clothes.

January 2nd, 1883.—Temperature normal; pulse 70. Strength returning. Able to walk about the room without assistance, and to sit up, daily, for a few hours. Heart

sounds as before; a soft systolic murmer, less defined. All fever and pain having left on the third day of my attendance.

January 7th.—Final visit. The patient's strength and flesh returning. Will soon be able to resume his employment. In this case I did not prescribe a single dose of medicine. Dr. Whitla was a witness to his convalescence. The blister was not yet healed.

I may here be permitted to quote from Dr. Whitla's excellent work on Pharmacy, Materia Medica, and Therapeutics, 1st and 5th edition, article Cantharides, page 389: "In *acute rheumatism*, blisters to the affected parts have long been advocated; but Dr. Harkin has pointed out surprising results obtainable by a large blister over the heart early in the disease (he believes it acts by curing the endocarditis, which some authorities consider always to be present, and to be the cause of the disease), and the writer has seen it reduce temperature and pain in a most decided way."

Case 13.—Mr. C——, a merchant, unmarried, sent for me on March 3rd, 1885. He was in bed complaining of pain in both ankles, right knee, left wrist; temperature at noon 100°; pulse 84; his second attack. In his previous attack, when fourteen years old, he was paralysed in every joint, ill for seven weeks, and had a relapse, and was confined to the house for thirteen weeks in all. I prescribed a Dover's powder and left. 4th morning.—Pains somewhat relieved, except in right knee and ankle, urine clear and plentiful, free perspiration; temperature 101°; pulse 80. Had a pressing call to see him at 8-30 p.m., and found him in high fever, pulse full and bounding, increased pain in left wrist and ankle and right knee; he was becoming impatient, having important business engagements, so, in presence of his friend, I applied the liquor epispasticus freely over the cardiac region, and left. 5th.—Much better, slept soundly; temperature 102°; pulse 80. Every joint improved, left hand still painful, left and right ankle nearly well, right knee still painful on pressure. His friend, who watched him all night, reported that as soon as the blister began to affect him—about an hour after its application—he became quiet, fell asleep, and did not awake till morning. He said he had read of miracles, but never witnessed one before. 5th, 8 p.m.—Temperature 101.4°; pulse 82. Left wrist still painful, other joints almost free, full power of motion restored. 6th.—Slept well, left wrist free of pain, all other joints perfectly well; no sweating, urine plentiful and neutral, able to walk about without pain; temperature normal; pulse 80. 6th, 8 p.m. —Feels perfectly well, but weak. 7th.—Slept well, every trace of rheumatism gone away.

The late Dr. John Meenan, surgeon to the Mater Infirmorum Hospital, Belfast, in a letter of thanks to me for some orginal papers, wrote: "In the only case in which I was able to try your treatment, it acted, as my patient remarked on the morning following the application of the blister, *like a charm*. The result, I must say, even exceeded my most sanguine expectations. I may remark that in the above case *I gave no medicine whatever*." Dr. Meenan had experienced in his own person, when a student in the Mater Misericordiæ Hospital, Dublin, as he informed me, the benefit of the blister, having had that remedy applied to his heart by the senior physician when ill of his third attack of acute rheumatism, with the result that he was able to don his clothes at the expiry of a week, having been confined to bed on two previous illnesses for seven and thirteen weeks respectively. This gentleman succumbed at last to another attack, complicated with hyperpyrexia, cardiac and pulmonary inflammation. I shall conclude by a reference to a paper published in the "Transactions of the Rhode Island Medical Society," vol. iii., part 2, March 20th, 1884, entitled, "Topical Cardiac Blistering in the Treatment of Acute Rheumatism," by Neal O'D. Parks, L.K.Q.C.P., of Ashton, Providence.

In Braithwait's retrospect for January, 1883, Dr. Alexander Harkin, of Belfast, Ireland, in an article entitled "Some Observations on Rheumatism and Gout, with a new departure in their cure," refers to thirteen consecutive cases of acute and subacute rheumatism, treated by himself and others by a topical remedy alone, without a dose of medicine practically being administered, in which the cure was in almost every instance rapid and complete. Dr. Harkin explains his theory thus:—"If it be physiologically true, that when two parts of the same body are nervously in sympathy with one another, if we produce a powerful effect on the nerves of one, we may draw vital energy from the nerves of the other, then it follows, that when a derivative in the form of a blister is applied to the nearest vicinity to the endocardial lining when in an inflamed state, it is but carrying into effect the principle that counter-irritation is the most effective plan available to alter the excited condition of nerve centres, and so to influence motor, sensory, and trophic nerves. Struck by the force of this reasoning, and the success of the treatment indicated, I resolved to give it a trial. Just then I was treating for acute rheumatism Mr. J. R——, of Ashton, whom, only a few joints being affected, I had treated by local blisters to the joints, and salicin in scruple doses, with carbonate of ammonia every hour. Under this treatment he improved, and in ten days resumed his ordinary pursuits. In a few days a relapse occurred, with pain and swelling of the knee and tarsal joints, and the evidence of an endocardial murmur. I forthwith ordered a blister, five by six inches, over Mr. R——'s heart, with the happy effect of aborting the relapse, all symptoms of which, including the endocardial murmur, quickly disappeared, urine and saliva became alkaline, and the patient has since then had no return of the malady. In the early part of last November I was called to an old lady, who every winter suffered from so-called rheumatic gout, which usually attacks each great toe in succession. On this occasion most of the joints of each foot, and some joints of the upper extremity, including the metacarpo-phalangeal joints of both hands, were involved with the usual accompaniment of great pain, swelling, and high fever. I ordered a blister over the heart, the joints to be anointed with ol. gaultheriae, which also was given internally fifteen drops every two hours. In three days she was able to sit up. As one of the finger joints continued swollen, I ordered another blister, but as the swelling began to subside she did not apply it, and in less than a fortnight she was out in her buggy, handling the reins herself, and to this date has had no symptoms of relapse. A friend who lives in Arlington, N. J., wrote me last spring that he was suffering from one of the annual attacks of rheumatic fever to which he is a martyr. I wrote to have him apply a blister to the region of the heart, and, on meeting him on my return from Europe last September, he told me that he could not have believed it was in the power of any remedy to have afforded such effectual and prompt relief, and he assured me that he has since then felt better in every way than for years previously.

I might multiply cases, but think the above amply sufficiently to warrant me in asking a more extended trial of this treatment upon the part of the profession. I have treated rheumatism by all the approved methods—alkaline, quinine, iodide of potassium, salicin, salicine compounds, blistering the joints, not forgetting calomel and opium, and have never before succeeded in laying the grim spectre of the inevitable relapse, that *bete noir* which was sure to hover around all the time-honoured methods of treatment. A great authority once said that the cure for rheumatic fever was "six weeks." My experience of the topical treatment is too limited to warrant me in more than expressing the hope that the time is drawing nigh when we might with truth exclaim, *nous avons changè tout cela.* It is possible that in the next case I may have to revert to the old dreaded two or three months type, but I must confess that I approach a case of polyarthritis rheumatica much more confidently armed with Dr. Harkin's remedy; and if its efficacy could be established in a large percentage of cases, the boon to suffering humanity would be simply incalculable; and if it should prove as potent in the hands of others as it has in mine (so far), and those of the author of the paper referred to, many an hour of suffering will have been spared, and much good conferred on suffering humanity. This paper having been prepared for the December meeting, I wish to refer to other cases occurring subsequently.

Case 1.—Mrs. M—— was attacked on January 24th, 1884; joints of left foot swollen, red, and painful. Applied to the præcordium a blister five by six inches, anointing joints with lin. camph. co. and ol. gaultheriæ, soda salicyl. fifteen grains, and ammon. carb. five grains every two hours. The following day the swelling was greatly reduced, joints soft and painless, and in two days she was walking about attending to her household duties.

Case 2.—Jas. M. D——, æt. thirty-seven, seen on January 27th, lying in bed in excruciating agony, unable to endure the slightest motion, not even of a person walking across the floor; joints of the right foot, knee, and hip, and the left hip-joint much swollen and painful. Was attacked two days previously, the foot-joints being first affected; pulse 100; temperature 101·6°; tongue foul; anorexia; rough systolic murmur at base of the heart. Blister five by six inches to praecordium; ol. gaultheriæ and lin. camph. co. to joints; salicin twenty grains, and ten every succeeding hour for four times, after that ten grains every two hours. January 28th—All pain gone except a little in the left hip-joint; no swelling; pulse 84; temperature normal; better and easier in every way; continue medicine. January 29th.—Pulse 84; temperature 99.4°; occasional pain in right knee, none anywhere else; profuse epistasis half an hour before visit; a similar attack two years since; feels weak. Continue salicin, with milk, beef tea, etc. January 30th.—Found him walking about the room, free from pain and swelling; tongue still coated; feels weak; heart sounds normal, but impulse feeble; tr. ferri. chlor. ʒ ss. diluted with water four times daily; continue salicin a few days more; blister to be dressed with ol. olivæ. The following week he resumed work, and on February 21st, a damp rainy day, he presented himself at my offce with a suppurating gland in the axilla. February 24th.—Found him complaining of grinding pains in hip in the course of the sciatic nerve pain and swelling in the left knee. Repeat blister and other treatment; temperature 102°; pulse 100. February 25th.—Pulse 84; temperature 99°; profuse acid perspiration; urine acid with copious brick-dust sediment; no pain in sciatic, nor in left knee; swelling gone. February 26th.—Pulse 84; temperature normal; excruciating pain near sciatic notch, and extending down thigh. Injected alcohol and amyl nitrite to back of thigh. February 27th.—Pulse 80; temperature normal; after this, in three days he was convalescent.

Case 3.—February 9th.—Katie A——, æt. eight years, ailing three or four days; left hip and all the joints of right lower extremity swollen and exquisitely painful; could not bear slightest touch or motion; pulse 120°; temperature 99.8°; tongue slightly coated. Ordered blister, three by three to præcordium; salicin ten grains; ammon. carb. five grains; every hour till five are taken, then every two hours; liniment as above to joints.

February 10th.—Much easier; pulse 100; temperature 99°; joints still swollen and painful—continue. Being in poor circumstances, her mother said if not better next day she would send for me; she did not do so. A week after I called, and found the child convalescent; the mother said she improved rapidly from the time I last saw her. On March 1st, the mother brought her to my office, appearing the picture of health.

Conclusion.—I think I have given sufficient proofs of the efficacy of this topical remedy, either alone or in conjunction with internal treatment, as some practitioners are too cautious to rely on it solely. If I have proved its power when given alone, in aborting acute rheumatism, (a remedy that could not possibly modify a diseased condition of the blood, or neutralise an acid poison permeating the system,) what becomes of the hypotheses of materies morbi, hyper-fibrination of the blood or uric acid poisoning, and the treatment dependent thereon. The success of this plan illustrates the truth of the axiom, propounded by Dr. P. Latham: "The treatment of diseases rightly considered, is, in fact, a part of their pathology. What they need, and what they can bear, the kind and strength of the remedy, and the changes which follow their application, are among the surest tests of their nature and tendency."[1]

Special Articles.

BIRMINGHAM SANITARY IMPROVEMENTS.

By Alfred J. H. Crespi, of Wimborne.

When due allowance is made for its immense population and great sanitary difficulties Birmingham is not such an eyesore to the sanitarian as some other large towns. Many of the local manufactures require ample space, and this makes it necessary to choose sites where land is comparatively cheap; moreover, new workshops are constantly springing up in the suburban districts, and from other causes the population of the town has unusual facilities for spreading over a large area. There are still some old, narrow, and filthy streets in the heart of the town, but not nearly as many as twenty years ago, and some in the outskirts are as wretched as anything to be seen out of London and Dublin. Some too, of the newer streets, are not all they should be, but, on the whole, Birmingham compares favourably with most large towns; indeed, I am not acquainted with any— and I know nearly every one of importance in England—which,

[1] Preface to "Lecture on Diseases of the Heart.

in proportion to its population, is not in greater need of sanitary improvements and better house accommodation, while some of the older cities, with only 40,000 or 60,000 inhabitants, have as many slums and fever nests as Birmingham. Exeter, where I once stayed seven weeks at a stretch, and which I have repeatedly thoroughly explored, is in a disgraceful state, and reminds me of Dudley and Oldbury; but even at Exeter they are moving, and a good deal is being done.

After all, these preliminary observations are hardly to the point. It does not signify that Birmingham is not worse than many smaller places, and better than most others of equal size. The question is, whether there are districts in Birmingham, which it would be desirable, in the general interest, to improve away, and from an intimate knowledge of almost every street and road in and near the town, I do not hesitate to say that, comparatively well off as Birmingham is, one-half the houses occupied by the working classes might with benefit be removed and replaced with better constructed and more wholesome dwellings. Even in Birmingham, in spite of rapid and great advance, whole streets ought to be cleared away, and their demolition would be attended with improvement to health and morals, and with diminished pauperism. Bad sanitary arrangements are paid for in increased disease, crime, poverty, and immorality, while well thought out sanitary improvements are always in the long run remunerative.

Extensive alterations in such a great city are impossible unless taken in hand by the municipality, although the movers in such improvements are bound to consult the commercial interests of the inhabitants as well as their health. The demolition of a large and populous district should be primarily undertaken for the diminution of sickness and pauperism, but beautifying the town and opening up better and more direct thoroughfares ought not to be forgotten, nor should an improvement scheme be suffered to drop because it is impossible to remove every fever den, and to open up every narrow street. The Artisans' Dwellings Act has given the municipalities, which have been wise enough to avail themselves of it, ample powers for good. Birmingham, always conspicuous in its zeal for reform, was, as usual, first and foremost, and schemes were soon broached for radically improving a large, old, and miserable district of the town. Mr. Joseph Chamberlain, as Mayor of Birmingham, showed, on many occasions, an earnest and enlightened wish to make his reign memorable in the history of the midland metropolis for useful reforms and much needed improvements. As long as an unkind fate kept him out of Parliament, he had more leisure to give his adopted town the benefit of wise plans and ripe experience, and it is undoubtedly to him, and to him alone, that Birmingham owes the prompt and extensive improvements, which were so long warmly discussed by the town council; and for years Mr. Chamberlain was the prime mover in every great measure.

The alterations talked of were these. It was proposed to cut a wide thoroughfare—a continuation of Stephenson-place, the short street leading direct to the London and North Western station—sixty feet to sixty-six feet broad, from the middle of New-street,—the principal artery of the town—through Union-street, Bull-street, Lower Priory, John-street, Stafford-street, and Moland-street, on to Aston-road, a distance of over a mile; and one or two splendid streets connecting the proposed thoroughfare with other important main streets, were also talked about, while several crooked and narrow lanes, notably Steelhouse-lane and John-street, were to be considerably widened. These improvements were greatly for the good of the town, and they would place the business parts in closer communication with one another. The most important feature of the scheme was, however, that many of the worst courts and lanes would be improved away, and the houses—in nearly all cases dilapidated and unwholesome—of 8,700 working-class people removed. The slums to be demolished covered over forty acres, an area little inferior to that of a small country town. But when once a fashion is set everyone is compelled to follow, and hundreds of houses, which no improvement scheme would have ventured to include, were demolished and rebuilt on a grander scale by their owners.

It is difficult to ascertain accurately the cost of these vast improvements. The estimated original cost of the area proposed to be dealt with was £1,303,221; but, as the Town Council expected that the value of the area, after its improvement, would be £846,262, the net cost would not exceed £461,959, or, say, half a million. Of course, too, the rateable value of the new shops and houses built on the cleared sites would be much higher than that of those pulled down, so that the income of the municipality, would, it was calculated, increase £6,000 a year. We cannot help admiring the care with which these calculations were made, and though amusing to find that a total of £1,300,000 was not considered near enough, nothing short of strict accuracy being tolerated, the figures now laid before the reader may be accepted as approximately correct. I cannot ascertain how much has actually been spent from first to last, but the original estimate must have been exceeded in an almost incalculable degree, and in the long run this cannot fail to be the to the permanent advantage of the town.

Can it be shown that an expenditure of half a million is justifiable, and will the advantages expected result? To both questions there is but one answer: the gain to the town has been immense, and its most strenuous opponents have long since held their peace.

The increased facilities for commerce, and the greater directness of communication will, in a very few years, be worth an incalculable sum, while the diminution of sickness, pauperism, and intemperance, and the fewer facilities for the escape of criminals are, from another point of view worth the money. I question whether Mr. Chamberlain ever proposed a wiser measure, or whether a large sum of money was ever more prudently laid out. Unless something very untoward should occur, it was certain that Birmingham would, in a few years, be busier, wealthier, and healthier, and time has fully confirmed the expectations which the best informed ventured to form. The chairman of the Improvement Committee, Mr. William White, was one of the best coadjutors Mr. Chamberlain could have. Not so brilliant an orator, he is, perhaps, as able a man of business. Respected and beloved throughout the district for his benevolence, sound common sense, and large administrative capacity, Mr. White is one of that class of upright, zealous public men, of whom England has good reason to be proud; men who ungrudgingly give time and thought to the service of their country, seldom receiving anything in return except trouble and expense, even their generous and unpaid labours not always exempting them from the censure of opponents and the jealousy of friends. Fifteen years ago Mr. White looked an elderly man, verging on sixty, but he has worn well, and I can see little change

in his appearance or manner, though no doubt he feels older.

I have said that the proposed improvements involved the demolition of hovels occupied by 9,000 working-class persons; but the original scheme included the building of better houses on the same ground, accommodating double that number. The new houses were to be larger, higher, and more convenient than the hovels they displaced; each was to be supplied with good water, and to have the best domestic offices that money and science could secure, but, fortunately, these palatial ranges of tenements have not been built, and it was found far better policy, as some people expected, to dispose of the land for first class offices and shops. One piece of advice was often pressed on the Improvement Committee:—It was, that Birmingham was fortunately circumstanced in that a comparatively small number of working-class people was obliged to come into a narrow area, in the middle of the town, every day to work. Huge blocks of tenements intercept air and light, and a dense population necessarily pollutes the air more than a scantier one; though there is no truth, as some sanitarians have contended, that the mortality increases in direct proportion to the density of population; were it so, such changes as those proposed in Birmingham would infallibly do harm, not good. Had it been necessary to erect model dwelling-houses, on the improved area, to accommodate three times the former population, there would, even then, have been a marked diminution of sickness and death. Still, speaking generally, it is better to avoid large and overgrown piles of tenements, and immoderate density of population. My own opinion is that a moderate walk, morning and evening, is beneficial to most working-class people. Even the air of Birmingham streets is purer and less unhealthy than that of ordinary workshops and sitting-rooms, and out-door exercise is useful to nearly all classes of workers. But we may safely leave the carrying out of the improvements to Mr. Chamberlain, Mr. White, their colleagues, and the more intelligent portion of the ratepayers of the town. If immense ranges of tenements should at any time be finally decided upon, it will only be because their necessity is undeniable; but with improved tramcars, additional railways, and more direct approaches, the population has spread out and is spreading out enormously, and overcrowding is undoubtedly diminishing. More than fifteen years have sped swiftly away since this magnificent scheme was first broached, and during the whole of that time the work of reconstruction has been going on, and it is still unfinished. Every fresh improvement seems to show that other improvements are needed, while all the alterations first proposed have not been carried out, so necessarily slow is the rebuilding of a great town.

How was the scheme received by the Town Council? On the whole, exceedingly well, and in a manner leaving little to desire. One or two gentlemen were anxious to suggest improvements, unconscious that the changes they proposed would lead to interminable discussions, calculations, and surveyings; others were desirous of pressing the claims of fresh districts, as though matters were not sufficiently complicated; while one or two Councillors—one of them, indeed, *mirabile dictu*, a medical practitioner—offered opposition on various grounds. But so that the Town Council entered heartily into the affair, it signified little what motives influenced some members.

The scheme was a grand and promising one, and was certain to prosper, provided its supporters kept close to the matter, and did not give rise to confusion and complications by making suggestions with little to recommend them, and if the proposed alterations were energetically entered upon and properly carried out. This was done, I am glad to add, and Mr. Chamberlain's long tenure of office will always be memorable for the blessings it has brought Birmingham.

I should be right in saying that no one, who had not seen the middle of the town for twenty years, would be able to find his way about it now. Vast areas have been cleared, reconstructed and opened up; the principal station, always large and worthy of such a town, has had its area doubled; thousands of houses have been swept away; miles of new streets have been cut; stupendous offices and warehouses now occupy the sites once filled by mean and dingy tenements; in short, the changes have been wonderful, and there seems no end to them. Still, all these costly and important alterations have not been improvements. Many of the new ranges of offices, which from the outside look palatial, are, when closely examined, dingy and ill-ventilated; while, though the width of the new streets is great, the buildings skirting them have been carried to such an immense elevation that light and air are much intercepted, and on smoky, foggy, winter days it would be hard to find any sight more depressing than a walk along those new thoroughfares. Unfortunately, the trees planted by Mr. Chamberlain have not resisted the foul air of the town; and the bright red-brick buildings, with snow-white stone dressings, have rapidly lost their freshness; and before many years have passed, some of the new houses will look little less dingy than did their predecessors. But how can this be prevented?

While the heart of the town has undergone such marvellous reconstruction, the suburbs have spread in all directions. Hundreds of acres of fields have been covered with villas and cottages; several additional parks have been presented to the town; and many institutions for the good of the working-classes have been founded. Birmingham has kept well abreast of the scientific and sanitary progress of the age, and has no reason to complain of the vast cost of the improvements. It has a lower sick- and death-rate, less pauperism and less crime, greater contentment, and greater regularity of employment, and every year sees advance in all those matters which increase the happiness and prosperity of its citizens.

THERAPEUTICAL NOTES.

From our Berlin Correspondent.

The modern treatment of Phthisis—Hot air Inhalation—Rectal injections of Carbonic acid—Therapeutic effects of Hydrastis Canadensis—Sulfonal in night sweating—Hydroxylamine — Tetrahydro-β-Naphthylamine — Picrotoxine an antidote of Morphia—A new mercury compound.

With the discovery of the tubercle bacillus, a fresh impetus has been given to all researches tending to throw new light on the question of treatment of phthisis. Indeed, a great number of remedies and cures have since been recommended, most of them with a view to "kill the bacilli." But none of them have lately attracted more attention than the following decidedly original and ingenious method:

Weigert was the first to recommend systematic inhalations

of air heated to a temperature of 350° F. But his publication found little favour, and a Berlin medical society positively refused to listen to one of his papers on the subject.

Professor Kohlschütter, however, has just now published a paper, in which he confirms the exactness of Weigert's theoretical deductions. He says that above all other things, Weigert has in his favour the property of the tubercle bacilli to be more influenced by changes of temperature than any other bacilli; that at a temperature of 38·5° C. they are materially weakened in their vitality, and that temperatures above 42° C. are fatal to them.

Kohlschütter put his patients under a course of Weigert's treatment, lasting seven weeks in each case. Of course he minutely watched the cases, and observed the following changes: considerable expansion of the thorax, so that its circumference increased from 89 to 95½ centimetres. Dullness, abnormal respiratory, and additional sounds disappeared, and a clear normal breathing was heard instead. More important than these favourable changes were the results of the examinations he made for estimating the quantity of bacilli contained in the sputa. Before treatment began there was a great number of bacilli in each cover-glass preparation. After some weeks treatment, of the preparations examined, the second contained none at all; the third perhaps four, etc.—altogether, some thirty. The examination was made very carefully so that no bacillus should be overlooked. He further states, that obviously a complete disappearance of all bacilli after seven weeks treatment cannot be expected; to kill all bacilli, including their spores, with one stroke, is quite impossible. None of the many anti-parasitic remedies at the disposal of the physician are able to do that. But if, he says, Weigert's method enables us to destroy each day a few more bacilli than there are actually produced, we have obtained a weapon against the great foe of humanity much more efficacious than any of those known up to the present time. He therefore thinks, that the method ought to be carefully considered, put to serious test, and not treated with sneering contempt, similar to that which was formerly accorded to hydrotherapy and massage by the scientific world.

With regard to the temperature, the Professor says that though the air in passing out from Weigert's apparatus has really the high temperature stated, that when entering the mouth it is of course somewhat lowered, but that even when exhaled the air has a temperature of 60° C., therefore a height sufficient to destroy the bacilli.

Rectal injections of carbonic acid constitute another modern kind of treatment for phthisis. Some interesting and very favourable results, obtained by this method, are published by Dr. M. Oliven in the *Therapeutische Monatshefte*. He comments on the property of the intestinal tract to readily absorb great quantities of irrespirable gases, especially of carbonic acid. When these gases have been introduced into the rectum, they are soon absorbed, and by the circulating blood carried to the lungs, where they are again removed from the body, becoming mixed with the ordinary expiratory air. The process forms a ready means by which powerful and equal action on all parts of the lungs is secured. But up to the present the method has found few supporters, partly for the reason of its complexity. This latter drawback has just now been overcome by making use of the ordinary fluid carbonic acid, which is sold in strong iron flasks, allowing the escape of a small and accurately measured quantity of gas.

For applying the injection Dr. Oliven recommends the following *modus procedendi:* The rectum is first evacuated by an ordinary warm water enema, then the patient is placed in a recumbent posture; a soft india-rubber catheter is introduced some inches up the rectum, and by bringing the apparatus into communication with the catheter, a certain amount of carbonic acid is introduced; the quantity of gas can be regulated by screws, and exactly measured by a manometer attached to the apparatus. He introduces as much as the patient is able to bear. As soon as the latter complains of a feeling of great tension, the inflation is stopped, and the *séance*, which on an average lasts from three to four minutes, is terminated. During each *séance*, from two to four litres of gas were introduced.

As regards the results of this treatment, the author states that fever decidedly abated, the temperature becoming normal, appetite and general health of the patients were much improved, and the distressing night-sweats diminished or entirely suppressed. He, therefore, confidently recommends the said method.

The same journal contains some very interesting therapeutic annotations by Dr. Böttrich, of Hagen. Speaking on the treatment of *Hæmoptoë*, he found opium, with acetate of lead, the most efficacious when the bleeding has just set in. It combines the action of hæmostasis and diminution of the cough. After two or three days he gave instead hydrastis, which drug he ordered from the beginning when the hæmorrhage was only slight. It had mostly a very decided effect. In one case of hysteric hæmoptysis its administration entirely stopped hæmorrhage after the first week. Also in cases of frequent bleeding from the nose hydrastis proved very serviceable, not against a single attack of profuse epistaxis, but against repeated recurrence of the bleeding. In such cases he has used the drug for the last two years, and he is very satisfied with the results.

Speaking on the action of *Sulphonal*, Dr. Bötrich says that a dose of eight grains was in most cases sufficient to entirely stop night-sweating. In this respect it equals the action of atropine, and has the advantage of being absolutely free from any unfavourable secondary effects.

Of late some new additions have been made to the long list of pharmaceutical preparations. *Hydroxylamine* is one of them. It is used in different skin affections as a substitute for chrysarobin and pyrogallic acid. Similar to those it has highly reducing properties when brought into contact with O-carriers. Its medicinal use was first proposed by Professor Binz, and first practically applied by P. T. Eichhoff, whilst it is known as a chemical substance ever since 1865, when Lössen obtained it by reducing nitric ether of methylene with granulated tin. Hydroxylamine is a strongly alkaline substance, which, combined with acids, forms well-crystallised salts. In a free state it is only known as watery solution. Its chemical formula is

$$N \begin{cases} OH. \\ H. \\ H. \end{cases}$$

which shows that it derives from ammonia, in which one atom of hydrogen is replaced by hydroxyl.

Hydroxylamini hydrochloras, or

$$N \begin{cases} OH.\ HCl. \\ H. \\ H. \end{cases}$$

is obtained by adding hydrochloric acid to the solution in

water. It consists of colourless hygroscopic crystals, soluble in water, alcohol, or glycerine. The solutions turn blue litmus-paper red, but leave Congo-paper unaffected.

Eichhoff used the following formula :—

℞ Hydroxylamini hydrochlor. .... gr. ii.
Spirit vini.
Glycerin. .....āā ʒ ii.
S. for external use.

After preparatory washing of the diseased parts of the skin with soft soap, this solution was applied from three to five times a day. It has been proposed to use ointment as a base, but the formula above is to be preferred, as the alcoholic solution penetrates the skin much more rapidly than ointments. The author has tried hydroxylamine in the following skin diseases :—Ringworm, sycosis parasitaria, and lupus vulgaris. Especially with lupus his results have been excellent. He furthermore thinks cases of psoriasis and chronic parasitic eczema suitable for the hydroxylamine treatment. He strongly advises further trials and experimenting with the new remedy, which has the advantage of combining cheapness with usefulness.

Not only Eichhoff, but also in the Vienna clinics an ointment of the following composition is employed :

℞ Hydroxylam. hydrochlor. ..... gr. ii.-viii.
Lanolini ..... ʒ iv.
Ol. olivæ ..... ʒ ss.

Another compound lately recommended as a therapeutic agent is the salt of tetrahydro-β-naphthylamine, which has the formula $C_{10} H_7 O_4 NH_2$. Filehne has used it as a 1-5 per cent. watery solution for instillation into the eye. It produced dilatation of the pupil, first of the eye where the solution had been used; after a short time also, the other pupil dilated, and the amount of mydriasis is said to be even more considerable than with atropine.

MONTHLY REPORT ON NEW PREPARATIONS,

FOODS, DRUGS, INVENTIONS, ETC.

Christia.—For some years Messrs. Christy & Co. have been working at a material (which they called christia) for replacing oiled silk, indiarubber or guttapercha tissues, etc., for the purposes of surgical bandages, sheets and plasters. The material consists of a thin, soft, and flexible tissue, prepared by a patented process, and, as will be seen from the following figures, it has in weight and in resistance great advantages over such substances as those referred to above, which cause sweating of the parts, and often induce irritation of the skin not less difficult to deal with than the ailment itself :—

Weight.—A bandage 11 feet long by $3\frac{3}{4}$ inches wide, ready for use, weighs one ounce.

Resistance.—A piece of christia 19 by $3\frac{1}{2}$ inches will bear a strain of 25 lbs. weight tied to it.

The stickiness of oiled silk and the rotten short fibre of gutta, to say nothing of the expense, are entirely overcome. It will be seen that christia is, from its lightness and strength, eminently suitable for bandages, surgical sheets, plasters, and waterproof linings or coverings. As an antiseptic or medicated bandage, owing to its power to absorb such antiseptics and remedies as carbolic, boracic and salicylic acids, potassium silicate, iodol, sozoiodol, iodine, etc., it is unique. Christia will prove a useful introduction in surgery, as it can always be kept handy in accident wards, ambulances, and dispensaries; it is strong, and of a minimum weight and bulk. It will be of service in the treatment of ulcerated or sore legs, which are so frequent with out-patients. The bandages will be rendered porous, so as to avoid the ill effects noticed with oiled silk and indiarubber tissues. Carbolized christia bandages have been submitted to several English hospital surgeons, and to army surgeons in Germany, France, and Austria, who pronounce it to be one of the most important and valuable introductions of the period in surgical bandages, and resulting from the opinions thus gathered, several forms of christia have been suggested, such as a combined bandage of christia and lint soaked in boracic acid; plasters and surgical sheets for operations. A series of samples can be obtained by surgeons attached to London and provincial hospitals, as well as by any surgeons who may desire to test this new advance in bandages and sheets. With regard to the name christia, it refers exclusively to the material, as far as it is made according to the patent, and that it will be described according as it is saturated, as carbolized christia, salicylic christia bandage, sheet or plaster.

Clinical Cases.

THE BINIODIDE OF MERCURY IN OBSTETRIC AND GENERAL PRACTICE.

C. R. Illingworth, M.D., M.R.C.S.

Puerperal Septicæmia and Peritonitis existing for seven days without treatment. Cured in four days with Biniodide of Mercury.

A. I—— was confined on January 20th, 1888. Forceps were used and the perineum was torn so that wire sutures were needed. On the 22nd or 23rd the nurse noticed that the lochia were offensive and used a vaginal douche of Condy's fluid. Sutures separated on fourth day. On the 24th there was intense pain in the hypogastric region and tenderness on pressure. Vaginal douche continued daily. No sleep since confinement. The pain continued and the patient got worse. Treatment directed to relieve biliary mischief and colic. On the 30th an anodyne draught given, as no sleep had been yet obtained. Some sleep obtained, but general condition the same. On the 31st I was called in consultation. There was marked cachexia; pulse 120, temperature 102.2° at noon, and great pain and tenderness on palpation in the pelvic region. I diagnosed puerperal septicæmia with consequent para- and perimetritis. The biniodide in sodic iodide of the strength of 1 to 2000 was at once injected into the vagina, the os being too contracted to admit the passage of the vaginal pipe to the fundus. The pain left at once and never returned. February 1st.—Had a fairly good night, sleeping at intervals. 9 a.m. Temperature 100°, pulse 100, respiration 20. 2 p.m. Temperature 100°. 5-30 p.m. Temperature 103.5°. Has no pain and feels well. 7 p.m. Chloroform; Sim's speculum passed; anterior lip seized with vulsellum forceps, and a No. 6 catheter passed for the purpose of syringing to the fundus by means of a Higginson attached with indiarubber tubing. Speculum revealed sloughing ulceration of the cervix, and brownish muco-purulent discharge from the os uteri. 9-45 p.m. Temperature 101.5°, pulse 112, respiration 23. Had an hour's sleep.

February 2nd.—1 a.m. No pain; Respiration 20. 4-40 a.m. Slept three hours and a half; temperature 98.4°; much refreshed; no pain; pulse 88, full, strong, and regular. 10-15 a.m. Temperature 103°. Chloroform given and injection used again, but not so successfully owing to the catheter slipping. 12-15 p.m. Evacuation of bowels helped by pressure of patient's hands on the lower part of the abdomen without causing pain. 3 p.m. Temperature 103°. 6 p.m. Has no pain and feels well; temperature 103.2°; operation repeated. The lotion smarted very much for an hour and a half afterwards. 9 p.m. Perspiring freely for first time. 9-30 p.m. Temperature 100°, pulse 100, respiration 24. 11 p.m. Temperature 99.2°, pulse 98, respiration 20. February 3rd.—1-15 a.m. Has slept; respiration 16, pulse 88, temperature 98°. 7 a.m. Respiration 16, pulse 88, temperature 98°. Slept soundly. 9 a.m. Slept since 7 a.m.; temperature 99.2°, respiration 18, pulse 98. 11 a.m. Temperature 103.5°, respiration 24, pulse 128. Injection of biniodide repeated in the same way, but again only with partial success from the same cause as before. 5-30 p.m. Temperature 102°, pulse 116, respiration 20. 9 p.m. Injection again, when a larger instrument—one of Mr. Allingham's double-channel catheters—was passed, and the strength of the lotion used was 1 in 3,000. Temperature before syringing, 100.4°. Smarting very severe, but immediately relieved by a solution of cocain applied with a brush to the os. At 11-30 p.m. Temperature 98.8°, pulse 104, respiration 18. February 4th.—3-15 a.m. Temperature 98°, pulse 100, respiration 18. Sleeps soundly and perspires freely. 6-45 a.m. Has slept soundly; temperature 98°, pulse 96, respiration 21. 2 p.m. Temperature 98.2°, pulse 108, respiration 17. Vaginal douche of 1 in 5,000 used. 8-30 p.m. Temperature 98.8°. Vaginal douche repeated. In comparing the effects of the intra-uterine injections, it is seen that in the incomplete ones the temperature was not thoroughly reduced; whilst the third complete one had the effect of permanently reducing it after two successive reductions to the normal, with a duration of fifteen hours before recrudescence.

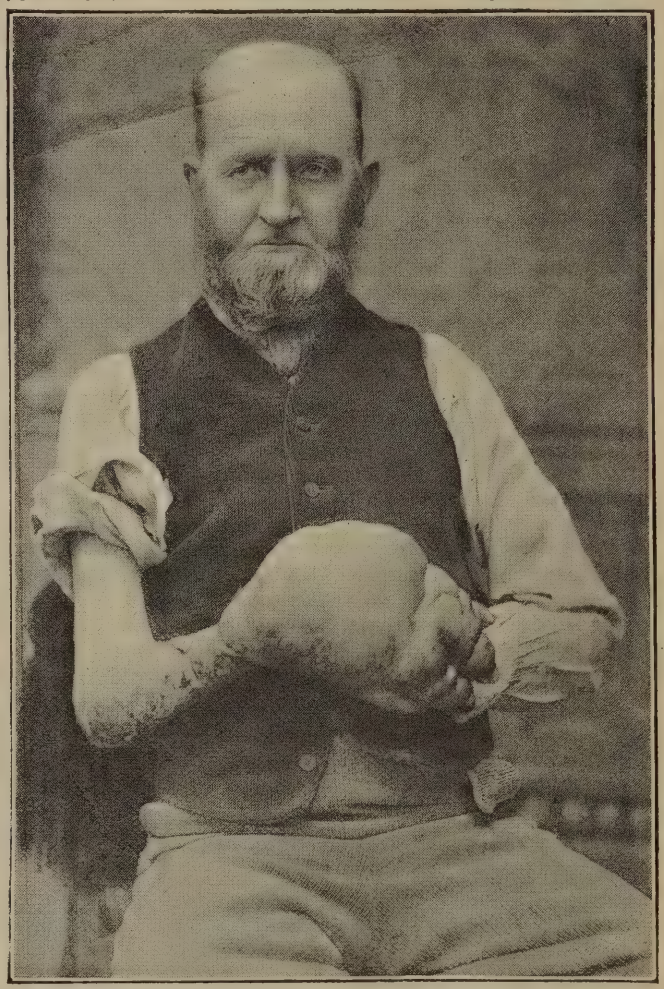
The diet was one of milk and barley water at intervals of two hours, and lemon water *ad libitum*. Medicine:—Four minim doses of the strong perchloride of iron, and two grain doses of chlorate of potash every two hours. The biniodide lotion is prepared as follows:—To six ounces of the B.P. liquor hydrargyri bichloridi, add forty minims of a 1 in 4 solution of the iodide of sodium. This gives a clear solution of the biniodide of mercury in the iodide of sodium, of the strength of 1 in 1,000. To this add a large teacupful of warm water at the bedside, and you have a solution for injection of the strength of about 1 in 2,500.

Remarks:—With ordinary antiseptics, such as carbolic acid, Condy's fluid, etc., this case, even if a cure could have been affected at so late a stage of the disease—which I much doubt—would have needed douching twice a day to the fundus for several weeks. The Laboratory Reports of the Edinburgh College of Physicians, contain in vol. i., February 5th, 1889, an account by Dr. Woodhead of experiments confirmatory of my statements regarding the biniodide, and the value of its solutions in the treatment of specific febrile disorders. But the sodic solution is superior to the potassic form used by Dr. Woodhead, because of the more penetrating properties of the sodium salts, due to their greater deliquescence. A spray of 1 in 2,000 is useful in diphtheria and scarlet fever throats. A lotion of 1 in 3,000 rapidly cures chronic discharges from the ear, and acute septic discharges from the eye, such as ophthalmia neonatorum. Other uses of the drug, since I first named the subject on May 1st, 1886, in the columns of the *British Medical Journal*, are mentioned in my work on the biniodide, published by Messrs. Lewis, 1888.

ELEPHANTIASIS OF THE ARM FOLLOWING A SEVERE BURN.—CASE OF HYPERTROPHY OF THE TOE NAILS AND LOWER EXTREMITIES.

By Wm. Berry, F.R.C.S.I.,
Honorary Surgeon Royal Albert Edward Infirmary, Wigan.

Case 1. *Elephantiasis of the arm following a severe burn.*—This case I saw in consultation with my friend, Dr. Tatham, the late Medical Officer to the Wigan Workhouse and Union. It occurred in a man æt. sixty years, of a feeble, pasty, cachectic appearance, and with albumen in his urine. Twelve years before, he had met with an accident, and burned his hand and forearm. It had suppurated for a long time; and as it gradually healed, enlargement and hypertrophy of the tissues commenced. Amputation had



been previously proposed, but this he refused. He was told this was his only chance of life, and notwithstanding his albuminuria, we decided to remove it, if he consented. After a few days consideration, he gave his consent; and in the meantime he had been put on a liberal diet, with a stimulant. Assisted by myself and my brother-in-law, Dr. Tatham removed the arm at the junction of upper with

the middle third, this being necessitated by the skin above the elbow being implicated. The man was very feeble for a few days, although there was not much blood lost, but

he rallied and recovered, the wound healing almost by the first intention. The pathological specimen was sent by Dr. Tatham to adorn the museum of Owen's College.

Case 2. *Case of Hypertrophy of the Toe Nails and Lower Extremities.*—This case came under my care in the wards

of the Royal Albert Edward Infirmary, Wigan. She was seventy-two years of age; had suffered for nine years from ulcerated legs, and been unable to walk about much, having lived by herself in a little cottage all this time, and seldom gone out. We put her on generous diet, and kept her in the horizontal posture for seven weeks, when she was discharged without any improvement.

A CASE OF EXOPHTHALMIC GOITRE; IMPROVEMENT.

By William H. Pearse, M.D. Edin.,
Senior Physician Plymouth Public Dispensary.

Mrs. A. H——, æt. twenty-eight, came for advice on January 23rd, 1888. Her appearance was most remarkable, owing to the extreme projection of the eye-balls. She dreaded going into the streets, from the constant observations of passers-by. She had a large goître, affecting both lobes of the gland. The goître and prominence of the eye-balls had existed for about a year. Three months prior to the onset of the eye-ball and thyroid affections she had an attack of quinsy. Up to four years of age she lived in one of the lodges of Mount Edgcombe Park, close to the sea; from thence she removed to Bungay, in Suffolk, where she lived ten years, leaving that place for Battersea, where she lived five years.

She had chorea during a period of three months when fifteen years old. She thinks that the eyes were prominent during the time she had chorea. The menses commenced at sixteen, and have been always scant and irregular, being absent sometimes for six and twelve months. At nineteen she returned from Battersea to Mount Edgcombe Park, where she lived a year. From that time to the present she has lived in Devonport and Stonehouse, with good hygienic surroundings. Two months after her return from Battersea her menses stopped, and her neck began to enlarge; her eyes became prominent, and remained so for ten months; the menses remained absent during the same period. She had medical treatment, and the protrusion of the eyes disappeared. She then married, when twenty years old. Had a miscarriage fourteen months after; was confined of her first living child two years after marriage. Up to the present time she has had three children. The eyes kept well until after the birth of her third and last child, two years ago. During the past four years she has suffered much from neuralgia in the head, face, and teeth. These attacks of neuralgia usually followed shiverings, which were associated with and followed by heats—such agueish-like attacks of shivering, heat, and neuralgia, happened every three or four months.

Viewing the history of the case, I could see but two main paths in her past—one was the want of vital energy, which was demonstrated by the scant and often-absent menses; the other was the possible influences of what we call "malaria," she having lived, from four years of age to fourteen, in Suffolk, and from fourteen to nineteen, in Battersea, both regions having a past history of prevalence of ague. Medical men who have lived in Bengal, Guiana, the West Indies, etc., will feel a wide expectancy as to the forms in which "malaria" (so-called) may result—*e.g.*, I have as surely seen herpes alternate with ague as that I have seen neuralgia follow ague; or again, I have seen diarrhœa, of many years' standing, in men who had lived in India, Lombardy, or Equador, cured by a treatment in which quinine was the main agent. Though the patient had never had ague in Suffolk or Battersea, it seemed just

to view the case as one in which a "malarious" (whatever may be the exacter meaning of that word) influence existed, and in a constitution of deficient vital energy. I use the words "vital energy" as implying the deficient evolution of the sexual function; and in speaking of the sexual function, we must follow Darwin—that the sexual function does not mainly lie in the sexual organs, but is pan-diffused throughout the "gemmules" of the whole system. The woman was, otherwise, of good physique, and of energetic mind and habits.

Under all the circumstances I gave her, once a week, a ten-grain dose of quinine dissolved in muriatic acid, and prescribed

℞

Quinæ Sulph.	gr. xl.
Liq. Ars. Hyd.	m.c.
Acid Muriat. dil.	ʒv.
Aq. ad.	℥x.

misce.

To make twenty doses. One dose to be taken three times a day after meals. Also half an ounce of cod-liver oil, daily, at bedtime.

At the end of four weeks the eyes became less prominent. There was ringing in the ears. The weekly dose of quinine was then reduced to five grains, but the mixture was continued. At the end of six weeks the eyes were almost, if not wholly, normal, and have so remained. The goître also lessened greatly, coincident with the improvement of the eyes. There is now a marked irregularity of the cardiac rhythm, but without bruit; this did not exist in January, 1888.

I do not venture to form any positive opinion as to the etiology of the disease in this case, or as to the value of the treatment; but I have thought the case worthy of record as illustrating the wide and generic relations of disease; and it may be, of opening up a part of the field of the pathology of exophthalmic goître.

Reviews.

Transactions of the Royal Academy of Medicine in Ireland. Vol. VI. Edited by Wm. Thomson, M.A., F.R.C.S., Dublin: Fannin & Co. 1888.

The goodly volume now before us, containing some five hundred octavo pages of well printed matter, may be regarded as being fairly representative of the work carried on by the profession in the sister isle. We may say at once that the work is carefully edited, that it is well printed on good paper, and that while eminently readable, it forms a solid contribution to the scientific work of the year. Amongst the numerous articles by various observers it would be hard to point to one which does not either add something to the ever-growing stock of medical knowledge, or present matter already known in a new or impressive form:—

"What oft was thought, but ne'er so well expressed."

From such a wealth of material we can manifestly select for reference only what seems of more than ordinary interest.

In the section of medicine Mr. Kendal Franks records a case which is a valuable addition to our knowledge of cerebral localisation, and which establishes the author's reputation as a careful clinical observer. The patient, a lady, was found after death to have been suffering from a cyst in the posterior part of the left tempero-sphenoidal lobe. Her symptoms were mainly epileptiform convulsions, transient "amnesic" aphasia, which seems to have been of the motor kind, and left-sided headache. There was also some amblyopia in the right half of the field of vision, which Mr. Franks ascribes to paresis of the external rectus, but which was more probably a partial hemiopia. Slight paresis of the right orbicularis palpebrarum, and of the right side of the face, were the only other localising symptoms; and in the present twilight of our knowledge we must commend Mr. Franks's decision, not to operate with such imperfect evidence of the seat of disease. In the light of the necropsy, we may clearly see that the aphasia, hemianopia, and paresis of the face were effects of the distal pressure of the cyst on the cortical centres around the fissure of sylvius; and should a case present a similar combination of symptoms at some future time, the experience of Mr. Franks's case might justify us in performing an exploratory operation.

Mr. C. J. Nixon points out that the prognosis is not inevitably unfavourable in cases with symptoms of spinal sclerosis, and that, whatever opinion we may form as to the real nature of the lesion, such cases not unfrequently end in complete recovery.

Dr. J. F. Knott records a case of purpura hæmorrhagica distinctly inherited, and ending by fatal epistaxis. He also contributes a paper on "The Fever of Over-exertion," which deserves a careful study, and whether we agree with the author's views or not, offers us much food for reflexion. The form of fever here spoken of is not described at any length in the ordinary text-books, but, according to Dr. Knott, is not uncommon in the rural parts of Ireland, and frequently ends fatally. At harvest time a man, who has been for months without employment and underfed, works at high pressure for several successive days to save the crops while the weather holds up. The unwonted exertion is followed by a feverish condition, the man is compelled to lay up for a day or two; but the call to the harvest field is imperative, and he returns to work while his temperature is still perhaps as high as 101°. The fever, which would have subsided after a few days' rest, becomes persistent, the pulse is permanently quickened, the usual symptoms of pyrexia become established. Gradual wasting sets in, the patient is confined to bed, and hectic supervenes. There is no ascertainable organic disease as a rule, but should there be any hereditary weakness of the lungs, phthisis may appear. The symptoms progress, and death ensues a year or more from the onset of the attack. Dr. Knott's view of the pathology of this condition is shortly as follows. The prolonged exertion that ushered in the attack threw into the blood a large excess of the products of muscular waste, which are powerful stimulants of the vaso-motor nervous system. The first effect of these products is to stimulate the vaso-motor centres, and cause contraction of the vessels, and if the mischief stopped there, no permanent harm would be done. But the supply of waste products is continued; the exertion, the *fons et origo mali*, is persevered in, and the continued stimulation of the vaso-motor centre leads to its exhaustion and paralysis. Vascular dilatation accordingly ensues throughout the muscular area; the undue supply of oxygen leads to accelerated combustion, and the consequent disengagement of heat overpowers the heat-regulating nervous apparatus of the body—the most unstable part of the

nervous system—and pyrexia is established. The author highly recommends the use of the organic acids in the form of grapes, and acid fruits in the treatment of this and other fevers, believing that they aid the elimination of the waste products of tissue metabolism. The Dublin school is justly celebrated in all that concerns fevers, and any suggestion for their treatment from that quarter will receive a respectful hearing from the profession.

Dr. James Little, whose infinite resource in the field of therapeutics is alike the admiration and the despair of his pupils, gives a valuable note on the use of saccharin as an antiseptic in chronic cystitis. His note on the treatment of migranous headache is also useful; but the administration of salicylate of soda for that condition is not original with him, having been recommended by Dr. Lauder Brunton in the Lettsomian Lectures for 1885.

Mr. Conolly Norman gives a graphic description of a case of Grübelsucht, a rare mental disease, in which the patient is possessed by an uncontrollable impulse to examine and investigate minutely every trifling object he meets with. We may say of the section of medicine that it maintains a fair average, but presents nothing of magnitude, either as regards the matter or the method.

The section of surgery is fully abreast of the times, and sustains the deserved reputation of the Dublin School in that department. Cerebral and abdominal surgery, which take so prominent a position in the present day, are well represented. An important case of mastoid and tympanic disease is related, in which Mr. J. Dallas Pratt successfully trephined, so as at once to lay bare the *dura mater* and open the mastoid cells, a method of procedure introduced by Mr. Wheeler, of Dublin. In this case perfect recovery resulted, along with the restoration of hearing. Sir Wm. Stokes, Mr. W. Thornley Stoker, and Mr. C. B. Ball, contribute each a case of successful operation on the cranium, showing the degree of precision possible in diagnosis, and the skill and courage of the operators. As a comment on these cases, we would lay special stress on the case related by Mr. Mayne, where, during the course of pyæmia, the patient was attacked by all the symptoms characteristic of abscess in the motor area of the cortex. No operation was attempted beyond trephining the mastoid cells, which led to no direct result, but the patient made a perfect recovery. Mr. M'Ardle's account of his case of enterectomy and enterorrhaphy is a monument of courage and manipulative skill, and deserves to be in the hands of every operating surgeon, who will find in it the fruits of the best and most recent labours in the field of abdominal surgery.

In the section of obstetrics, Dr. Kirkpatrick adds his mite to the vast store of learning that has been expended on the vexed question of the management of the perineum during labour. The proverbial difference of doctors here finds an apt illustration. Dr. Kirkpatrick quotes some dozen authorities, each of whom gives his own peculiar view as to the treatment that should be adopted, ranging from a policy of absolute non-intervention on the one hand, to, on the other hand, an officious meddling with the perineum which might well bring about the laceration we desire to avert. We are disposed to infer from this that—as in the other processes of labour, so in this—unaided Nature may generally be trusted to take care of the structures; but Dr. Kirkpatrick has adopted a method of his own for protecting the perineum, which he thinks yields more successful results than the others. As, however, the twelve authorities above referred to would probably say the same of their methods, we do not think it necessary to burden the mind of the busy practitioner with this one.

The section of pathology contains, among many interesting contributions, an account of a fatal suicidal wound of the heart inflicted with a pin. The pin was about $1\frac{1}{2}$ inches long, and was driven down to the head through the fifth intercostal space at the point of greatest impulse, and left *in situ*. The movement of the heart caused extensive laceration around the puncture, and death resulted from hæmorrhage into the pericardium.

Perhaps the most important contribution in the whole volume, and the one that will hold its place longest in the annals of medicine, is the account given by Dr. C. Y. Pearson of the medical aspects of the Coachford poisoning case, which will probably be familiar to most of our readers as the Cross case. It will be remembered that Surgeon-Major Philip Cross, of Shandy Hall, was convicted in 1887 of the murder of his wife by the administration of arsenic. Dr. Pearson was the principal medical witness for the prosecution, and made a *post-mortem* examination of the body of the deceased seven weeks after death, when, owing to the antiseptic properties of the poison, decomposition was no more advanced than if death had occurred a day or two before. Ulceration of the stomach, generally regarded as one of the signs of arsenical poisoning, was entirely absent. The chemical processes carried out by Dr. Pearson, by which the presence of arsenic was demonstrated and its amount estimated, are circumstantially narrated, and the case is a model of the way in which a medico-legal investigation of this kind should be conducted.

Before taking leave of the volume, we cannot help drawing attention to the beautiful dissection by Dr. Brooks, figured in a plate near the end, and illustrating the distribution of the nerves in the dorsum of the hand. From this dissection it appears (as we have had occasion to suspect from clinical observations) that the nervous distribution is not nearly so simple as it is generally represented to be, but that the radial and ulnar nerves interlace, so that it is only near the outer and inner borders of the hand that the nervous supply is single.

T. R. Bradshaw, M.D.

Elements of Histology. By E. Klein, M.D., F.R.S. pp. 368, small 8vo. London: Cassell's. 1889.

Looked at from the point of view of size or weight, this must be spoken of as a *little* book; but considered with regard to its contents, it can only be looked upon as a large and comprehensive volume. It will not be entirely new to some of our readers, since it is a new and enlarged edition of a manual that has gone through several editions, bringing up the researches of histologists to the level of the present time. The author observes, in his preface: "The time has now arrived when, owing to the constant progress in histology, several points have become clearer and considerably advanced. Thus in the question of the division of the nucleus, then of recent origin, many valuable and exact observations have brought this to a much better understanding. Likewise the termination of nerves in the epithelium and epidermis seems to become more settled. . . . The termination of nerve fibres in striped muscular tissue has, by Kühne's recent researches, been considerably

advanced; and in the chapter on the structure of striped muscular tissue, I have adopted Rollet's recently published views." New and original illustrations have been added, including also 194 micro-photographs by Mr. Andrew Pringle. Without these illustrations it would be a matter of impossibility to follow the text; but, with their help, the structure of each tissue becomes clear to the reader. A copious index affords a ready reference to the histology of every tissue and organ, and presents at the same time a complete glossory of the scientific terms which have necessary become multiplied with the advances made in the anatomical sciences. Students of human histology have much reason to be thankful to Dr. Klein for this exposition of researches by himself and other investigators.

W. Kesteven, M.D.

The Essentials of Physical Diagnosis of the Chest and Abdomen. By J. Wallace Anderson, M.D.

We scarcely think the excuse made use of in the preface, and which the author puts forward as the reason for his production of this little work, was needed. Whether there be other such guides in existence, we are distinctly of opinion that there is room for the work now before us. The physical signs of disease, as they present themselves to such a man as Dr. Anderson, and described in his own words, cannot fail to be valuable not only to the medical student, but to the medical practitioner. Dr. Anderson evidently possesses an acute sense of hearing; but we doubt whether all men are similarly endowed; and while he rather deprecates the various means, such as pleximeters and double stethoscopes, which men not equally endowed with himself find it advantageous to use, and urges the use of the ordinary tube stethoscopes and the fingers, we fancy that he does not make sufficient allowance for different degrees of auditory power. Possibly there might be some improvement in the value of the work to the student and to the practitioner if a little more had been said as to the use of the stethoscope in abdominal examination—*e.g.*, in pregnancy; but on the whole the book is most valuable, and we cannot help thinking that if other medical teachers of mark were to publish similar works, each giving his own ideas, educated by long experience, as to the nature and cause of the various phenomena met with in the physical examinations of the human body, that the profession as a whole would gain thereby. W. H. K.

The Treatment of Lateral Curvature of the Spine, with Appendix on the Treatment of Flat Foot. By Bernard Roth, F.R.C.S. London: H. K. Lewis. 1889.

In this monograph and appendix of fifty-six pages are embodied the views of the author on the causation, diagnosis, and treatment of these troublesome deformities. Those who have read Mr. Roth's article on "Lateral Curvature of the Spine" in Heath's "Dictionary of Surgery," and also his papers on the same subject in the *British Medical Journal*, the *New York Medical Record*, and the Clinical Society's *Transactions*, will find little that is new in this volume; but our daily experience teaches us that, although Roth's views have been before the profession for several years, there is even yet a large number of practitioners who still pin their faith solely to the teachings and practice of the old "spinal support" school, and to this class in particular we would strongly recommend this book. There is another and even larger class who would profit by carefully studying Roth's writings—viz,, those practitioners who meet with cases of lateral curvatures at their earliest onset, and who advise friends that the patient will grow out of the deformity in time. It is quite certain that lateral curvatures of the spine can be cured only where there is no osseous deformity, that is in its early stages, during the period of what Roth calls "postural deformity." Although the title of the volume comprises treatment alone, there are suggestive pages on causation, mode of examination, symptoms, and diagnosis. Weakness of spinal muscle is the predisponant, and the position of writing, as generally practised, is the most frequent exciting cause. Rickets, or anything which weakens the muscular system, tends to produce lateral curvature. All cases may be arranged in two large groups, quite irrespective of their causation—namely (1) those without any osseous deformity of the ribs or vertebræ, shortly the "postural stage;" and (2) those with osseous deformity—"osseous stage"—which may be conveniently sub-divided into (*a*) slight, (*b*) moderate, and (*c*) severe, or extreme. Every case of lateral curvature, with the exception of those with extreme osseous deformity causing complete fixation of the vertebræ, presents at least two erect postures: one when the patient is in his habitual position, and the other when placed in the best possible position by the surgeon. It is with regard to the latter that accurate observations only can be made as to the effects of treatment. "The only rational and really successful treatment of lateral curvature," says Roth, "is that which I have the honour to advocate—that is, re-education of the muscular sense of the best possible position, and methodical exercises of the muscles to enable the patient to maintain this improved position without effort, or, to put it more shortly, 'treatment by posture and exercise.'" A committee specially appointed to enquire into this malady by the Clinical Society of London reported, about two years ago, that "the amount of improvement which may be hoped for in any given case may not unsafely be gauged by the improvement which the patient can voluntarily effect (directed or helped by the surgeon) in his or her position when first seen." The principles which underlie the method of treatment advocated by Roth may thus be summarised: (1) Re-education of the patient's muscular sense as to an erect or improved position. (2) Improved position to be maintained at all times while sitting or standing. (3) Attention to dress. (4) Systematic training of the spinal and other muscles, including the development of the thorax. (5) Attention to general health. (6) Subsequent home treatment to prevent relapse in the improvement or cure that has been obtained by the surgeon. One of the essentials of Roth's treatment is that the surgeon himself should carry out certain of the daily exercises, and this, we think, constitutes the difficult feature in the method. The majority of patients cannot possibly obtain such daily attendance, neither can the majority of practitioners find time to give them. It is the rich few only who can afford the luxury of a three-months' residence in a surgical home, and in our opinion it is very rarely necessary. We have obtained excellent results by a judicious arrangement of periods of rest, regular gymnastic exercises, and some kind of mechanical support—a combination of agents precisely similar to those adopted in the treatment of any other deformity depending primarily on muscular debility. We agree with Dr. Roth in condemning the practice of trusting to instruments alone in the treatment of "scoliosis," but we differ from him when

he says that they do absolutely no good except in cases of curvature due to "paralysis of spinal muscles."

The observations on the association of flat-foot and lateral curvature are interesting, and well deserving of our careful attention. The book is enriched by photographs of cases and diagrams of osseous deformities. JORDAN LLOYD.

Short Notices.

De L'Origine et de la fin de la terre et de l'homme. By JEAN CROCQ, junior (*illustrated*).

AMONGST the leading doctrines of contemporaneous science, none is more wonderful or more suggestive than that of evolution. The idea of evolution may be discerned in the writings of the philosophers of antiquity, and the science has been built up by Lamarck, Darwin, and Hæckel, on a foundation which consists of an enormous aggregate of scientific observations. It has become the basis of a general philosophy which explains the universe, animated nature, and every manifestation of human activity, from the scarcely articulated language of the barbarian to the highest conceptions of the thinker; from the rudimentary customs of savage tribes to the complex social life of civilised nations. The young author treats in this work of all that is essential in the doctrine of evolution, and he condenses in a few pages the huge array of arguments which different sciences bring to support the theory of a perpetual future: astronomy, geology, biology, embryology, paleontology, etc. M. Crocq differs from the well-known genealogical classification of Hæckel and as an alternative provides a classification of his own, to which he invites the attention of the scientific. His work, however, is not addressed exclusively to the scientific world, but also to the general public for all is lucidly explained. The treatise may be commended from every point of view, and should have a wide circulation. H. R. H.

Travaux d' Obstetrique. By DR. AUVARD.

THE author, who is gifted with remarkable powers of explanation, and whose literary style is most agreeable, has compiled an excellent work in three volumes. The first volume is devoted to a series of memoirs collected from various sources, most of which may be met with in other treatises. The second volume contains some interesting original matter, such for instance as the relations of the puerperal condition to obesity and the influence of suckling on the obese. Contrary to the generally received opinion, Dr. Auvard holds that it is the posterior shoulder which is first born after the head in natural labour, and when it is necessary to assist the birth of the shoulders the first to be brought down is that which is situated posteriorly. In the chapters devoted to the treatment of *post-partum* hæmorrhage, the author advocates, after the failure of the more usual remedies, the plugging of the uterine cavity, for which purpose he uses strips of iodoform gauze (20 per cent). These strips are folded longitudinally in eight folds. The tampon should remain in the uterine cavity twenty-four hours, when it may be withdrawn by gently drawing the extremity of the strip which unfolds itself. There is an excellent chapter on the appendages, on injuries to the vulva, and the *post-partum* elevation of the uterus. The third volume includes a complete study of the delivery of the head when it is born after the rest of the body, and amongst other valuable chapters may be mentioned those on lateral obliquity of the gravid uterus, sudden death during labour, and the diagnosis of the period of utero gestation. The work is a valuable addition to obstetric literature. H. R. H.

Traité Elementaire d' Hygiene et de Therapeutique de l' Hysterie. By DR. GEORGE THERMES.

AFTER a very careful discussion of the difficult question of pathogenesis in the hysteria both of the male and female; the author devotes considerable space in the earlier chapters to the treatment of the neurosis, and to a regulation of the personal hygiene of the patient. He then passes to the study of therapeutic treatment in its literal sense, and reviews the agents which have revolutionised in later days the treatment of hysteria. He dwells most on hydro and electro therapeutics. The question of treatment in special institutions is discussed in all its details. The work concludes with a short chapter on hypnotism and suggestion. Dr. Thermes may be congratulated on not having devoted too much space to these new methods, the employment of which is so questionable in the hands of practitioners who are but slightly acquainted with the peculiarities and the tricks of the susceptible. H. R. H.

Recherches Cliniques sur les Anomalies de L'Instinct Sexuel. By DR. PAUL SERIEUX.

THE author adops Magnan's classification, and describes seriatim the different varieties of perverted sexual instinct, based on his own observations, most of which are unpublished. He shows that epileptic and hysterical patients should be divided into two groups according to the morbid manifestations of genital life; those which are of truly sexual origin, and those which are produced in the interval of the attacks and which belong to the mental condition which accompanies the neurosis. His general conclusion is that sexual psychopathies must not be considered morbid entities, but rather symptoms of very varied pathological conditions; mental degeneration, mania, melancholia, hysteria, epilepsy, confirmed delirium, senile dementia, or general paralysis. H. R. H.

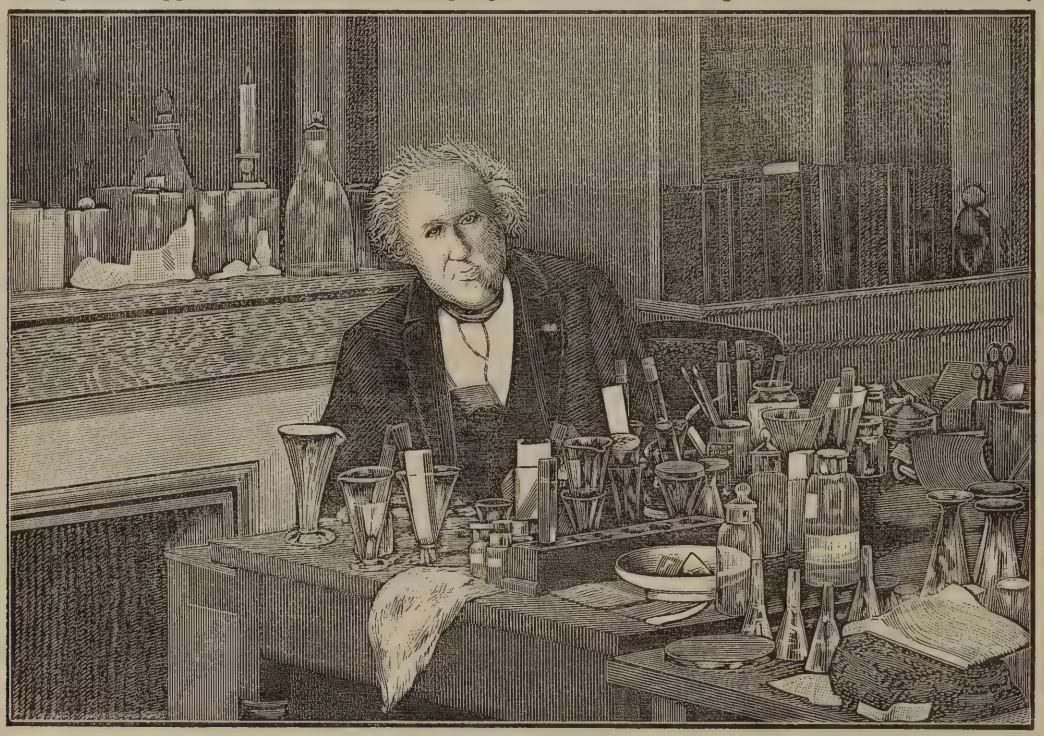
Notes on Physiology. By HENRY ASHBY, M.D. Lond., M.R.C.P. pp. 362, small 8vo. London: Longmans, 1889.

A FIFTH edition of this work requires little more at our hands than the announcement of its thorough revision, with the addition of new matter and new woodcuts, constituting the volume what the author justly designates a "*resumé* of the principal facts of the science"; indeed it would not be easy to find a more concise and correct summary of the "facts" of physiological science. It is adapted equally to the requirements of the student, and of the practitioner with scant leisure for the consultation of larger, or more elaborate, treatises. The former will find it an invaluable help in the study and in the dissecting room; the latter will have at hand a "refresher" to his memory in matters physiological, pathological, and therapeutical. W. KESTEVEN, M.D.

The Provincial Medical Journal,

MAY, 1889.

THE death of a centenarian is at all times remarkable, but the death of one of the most eminent chemists of the day, at this advanced age, makes the event all the more worthy of notice. M. CHEVREUL was born 31st of August, 1786, and was, therefore, in his 103rd year. It is only by a comparison or retrospection that we can really estimate what such an advanced age means. What happened 100 years ago is ancient history to most of us. M. CHEVREUL was a baby when MARIE ANTOINETTE was on the throne of France. He witnessed all the horrors of the Revolution. He would then be about seventeen years old. He saw dynasties and empires disappear, restorations of Kingships and Republics, fortunately preserving amidst all the changes his head—in more senses than one. His son died at the age of sixty-nine—an old man, but young in comparison with his father. M. CHEVREUL was descended from a medical family, who were also long lived. His father was MICHEL CHEVREUL, Master of Surgery and Doctor of Medicine; his grandfather and great uncle were also Masters of Surgery. His father lived to the age of ninety-one, and his mother to the age of ninety-three. He inherited from them not only health, but perseverance, great sense, and talent. After his preliminary education at Angiers, he went to Paris and entered the laboratory of VAQUELIN. His progress was so marked, that at the age of twenty VAQUELIN gave him the direction of his laboratory. About this time he devoted himself to teaching at the Charlemagne College. At the age of thirty he was appointed director of the dye works and special professor of chemistry at the Gobelins. His researches have taken a practical form, and resulted not only in wealth to himself, but wealth to others. In 1814 he demonstrated the existence of *oleine*, *margarine*, and *stearin*, as component elements of oils and fats; his theory of saponification, and his labours in connection with fats, not only created new industries, but widened the horizon for organic chemistry, and opened the way for other discoveries. Turning his attention to the science of colours, he reduced the alliance of colours to exact scientific laws, and in 1864 his book upon this subject, reproduced the labour of many years, having been preceded in 1828, 1831, 1839, and 1848, by memoirs on this subject. In the latter work M. CHEVREUL traced the rules of those undulatory and fugitive



M. Chevreul in his hundredth year.

effects produced by the colours of walls, fabrics, and clothing upon the flesh colour of human beings, and even went so far as to relate to the arrangements of flowers, and ornamental plants and plants in gardens. His enunciation of the laws governing the simultaneous or successive contrasts of colours, the theory of coloured shadows, and the art of defining by means of a chromatic circle every shade by a figure, has enabled the reproduction in foreign countries, and without seeing them, the tones of a fabric or tints of a picture painted in Europe. In 1826 he was elected to the vacancy in the chemical section of the Academy of Sciences. In 1830 be became Director of the Museum, and so continued until he relinquished it to Frémy in 1883. For many years he was examiner at the Polytechnic School. He has

also been President of the National Agricultural Society. All the leading scientific bodies of the world, such as the Royal Society of London, and the Scientific Societies of Copenhagen, Stockholm, Berlin, Moscow, Philadelphia, and others, have included him among their foreign members. Until 1855 he had been a member of the jury of every French exhibition. He became a member of the Legion of Honour, and in 1844 was a commander; a grand officer in 1865, and in 1875 he received the grand cross. The foreign decorations that he has received would cover his entire breast. His life has been passed between the Museum of Natural History, the Gobelins tapestry works, and the Institute of France, and he has never failed to be present at the Monday meeting of the Academy. The number of memoirs of which he has been the author are almost incalculable. During the Franco-Prussian war (1870-71) he remained within Paris during the siege, living at the Museum even while more than eighty Prussian shells were shattering the galleries and breaking the cases. It seems but the other day he was celebrating his hundredth birthday, when he received the congratulations of the whole scientific world. Up to that time he had never known what it was to be ill, he had never been incapacitated a single day owing to illness, and had never had an extra holiday. Work had not worn him out. He must have been of an evenly balanced mind to have passed through the political crises of his country, so unmoved as it were. Science was all in all to him, and for her he evidently lived. The principle of life inherited from his parents was fortified by his abstemious and methodical habits. M. Chevreul outlived his cotemporaries, and though a new generation had sprung up about him, yet when he went about the streets of Paris he did not feel like Rip Van Winkle. He kept himself *au courant* up to the last with what was going on round him, and only a short time before his death he was driven to see the Eiffel Tower, upon seeing which he said, "What a splendid sight. I always gloried in science. What cannot science do?" We are indebted for some of the above facts to the *American Druggist*, as well as for the drawing.

In the hurry and bustle of to-day, in the desire for change and novelty, but too little attention is paid to what has been done in the past, and too little credit given to the pioneers who made the operations of to-day possible. When but a few years ago we were told that the peritoneum might be opened with comparative impunity, it fell upon the profession as an absolutely new idea, as one that had never been thought of before; and the bolder abdominal surgery of to-day is also thought to be new by the general bulk of the profession, who naturally have not time to read up, or to dip into the pages of the past. It does not detract, of course, from the merits of the operators who have carried to perfection the abdominal operations which stand out as veritable triumphs of surgery, that their ideas have been forestalled, and they may well afford to have their laurels shared with competitors whose bones are mouldering in the dust. Amongst the men of the past who conceived the prospects of a bolder abdominal surgery, John Blundel stands out most prominently, and he has left us a history of his schemes in an 8vo. of 146 pages (two plates) entitled: "Researches, Physiological and Pathological, instituted principally with a view to the Improvement of Medical and Surgical Practice." We may mention here that Blundel was Lecturer on Physiology and Midwifery at the united Hospitals of St. Thomas's and Guy's. Blundel was remarkable in being the precursor of the school about which we hear very much at the present day—the school of experimental physiology; and he, like the modern school, selected the rabbit, and performed on this animal a number of experiments, which have been repeated during the last few years. Blundel was under the impression that abdominal surgery might be very much improved, and he tried what the rabbit could stand. For instance, he extirpated the left kidney of four rabbits, all of whom died. He removed the spleen from seven rabbits: two died, one survived three months, one six months, the sixth and seventh recovered permanently. In order to test the effects of injury to the bladder he injured the bladder of two rabbits: one survived six months, the other survived permanently. He injected human urine into the peritoneum of four rabbits, and left it for an hour, and then washed it out: one rabbit survived this operation. These are a few instances of the class of experiments he carried on, and from them he deduced the conclusion that moderate opening into the human peritoneum would not necessarlly prove fatal; and further, that certain parts, not essential to the welfare of our structure, may be removed from the belly without necessarily or even generally producing death. "The extirpation of the kidney," he says, "must be highly dangerous, but there is a presumption in favour of the successful removal of the spleen, the ovaries, or even large pieces of the bladder." He gives a number of instances in which important organs have been removed from the human body without death. He proposed a number of operations:

1. He suggested that a portion of the fallopian tubes might be removed, so as to prevent pregnancy in deformed pelvis.

2. He forestalled Battey by suggesting the extirpation of healthy ovaries, which he said would be an effectual remedy in cases of dysmenorrhœa.

3. He favoured the removal of a cancerous womb when ulceration first makes its appearances.

4. He suggested the removal of the puerperal uterus.

5. He advocated gastrotomy for intussusception.

6. An operation for injury of the bladder has just come prominently to the front, and rupture of the bladder we know now is not necessarily fatal. Blundel is very clear on this: "Should the bladder give way," he said, "into the peritoneal sac, why should we not lay open the abdomen, tie up the bladder, discharge the urine, and wash out the peritoneum thoroughly by the injection with warm water."

We have given, we think, sufficient instances of BLUNDEL'S great surgical foresight. We fear that a number of young experimentalists have hardly heard of BLUNDEL'S name, because they seem to be repeating the very same experiments which he performed over sixty years ago, and which are already established among the facts of medicine. Their experiments, of course, will be new to a certain number of the profession, but those who take up experimental physiology should be fully acquainted with what has been already done by the older experimenters.

THE impecuniosity of the hospitals is now admitted. They are bankrupt, because they have been trading on absolutely unsound principles. Charity has been abused, and the sick poor—for whom hospitals were originally intended—have been displaced by another class, who have taken advantage of the liberal offers held out to them. A commercial firm trading as the hospitals have been trading of late years would end in the bankruptcy court, and the judge would certainly be bound to read a very solemn lesson on the false system which led to insolvency. The hospitals are before the bar of professional opinion, and there is universal condemnation of the whole system. In spite of the verdict of the profession, the promoters and philanthropists of the hospitals are issuing appeals for more money, and in our large provincial towns new contrivances are started to bring in supplies. We published in the April number the views of a general practitioner on the hospital system, and from numerous letters we have since received we have reason to believe that those views are very generally accepted. One correspondent writes to say "that he has contributed £60 a year for the last ten years to his infirmary. I do not wish you to understand that I have given this in money, but this is the amount of money I have lost by the operatives, and other persons in good position, who have gone to the infirmary for free advice; without the hospital, they would have come to me. I do not object to surgical wards, or the treatment of cases requiring nursing and rest, but I fail to see why we should have out-patient deparments, where common ailments are prescribed for. I have had repeated opportunities of seeing the class of people who attend as out-patients; the majority of them are well able to pay the very small fee required by the general practitioner. A greater evil still is the custom at some infirmaries of visiting patients at their own homes."

Several other correspondents have written to the same effect. When the provincial infirmaries were first organised, the Poor-law system was very different from what it is at the present day. The sick poor required institutions of the kind, and subscribers gladly gave their money, and medical men their services, for such excellent objects as the relief of deserving sick. But the infirmaries opened their doors wider, and competition began; the greater the number of patients relieved, the greater good was supposed to be done. Hence all classes were gathered in the net. Poverty was not the first claim. Subscribers gave their guineas a year, and receiving books of tickets, they distributed them widely, thereby securing a very excellent return for their money. In process of time, subscriptions not coming in so freely, though the portals were so widely opened, Hospital Sundays and Hospital Saturdays were instituted, and appeals were made to the working-classes. We know of no class so intelligent as the latter. Their thrifty habits, and their saving propensities are deserving of the highest commendation: they have organised sick clubs, burial clubs, co-operative stores, and have in various ways tried to provide for a rainy day. When the hospitals threw open their doors to them, and invited contributions, they readily fell into the scheme, and they gave their pennies; but they expect something in return, but something out of proportion altogether to their donations, and something they could only receive at the expense of the profession. For instance, the working-men of Halifax gave £1,000 during the year 1888, but the work of the institution has now so much increased, that a new infirmary is required, and the governors have issued an appeal for funds. It would not be too much to say that for every shilling contribution of the working man, 20/- is returned by the profession. The chief factor in these institutions is the advice, and that is given gratuitously; the field of practice by this is much diminished, and the general practitioner loses possible clients. It comes to a question of supply and demand, and to one of trade. When the working-classes find the hospitals open to them on such very easy terms, they would be very unwise not to accept what is offered. The abuse of the hospital system in some of our large towns have compelled the profession to move in the matter. Meetings have recently been held at Birmingham, and a strong committee has been appointed to draw up a scheme which will protect the profession. It must be clearly understood that the profession is always willing, as it has been before, to do charitable work; but the hospitals are no longer charities, they are taking the place of the working men's sick clubs. This state of things cannot be allowed to continue without some protest from those who are so pecuniarily interested as general practitioners are. The profession in Birmingham, of all grades and classes, are united on this point. It is admitted that in Birmingham the hospitals are abused, greatly to the injury of the profession at large, and a scheme will shortly be issued which will in a certain measure correct the evil if properly carried out. The Provident Dispensary system has not given general satisfaction, and we believe will not be tried at Birmingham; but in its place numbers of dispensaries will be established all over the town, so as to place within the reach of the poorer classes medical advice, which will in some cases be given gratuitously, and in some cases be charged for. This will relieve the pressure on the hospitals; and as a vigorous system of examination of cases will be adopted, the frauds at present perpetrated on our charities will be prevented. We shall publish full details of the scheme in our next issue, because Birmingham is not the only town where the hospitals

are abused. This is a question for the general practitioners to take up; they can only check the abuse of hospitalism by union amongst themselves. The old fable of the bundle of sticks has very much force. The application of the lesson lies with them.

We have written several articles on the subject of antiseptic midwifery, and we have insisted upon the absolute necessity of cleanliness, and the power cleanliness has, apart altogether from antiseptics, of keeping the mortality down. We proved by statistics, taken from workhouse maternities, that a mortality not exceeding four per thousand may be obtained, and that even this mortality may be lowered in private practice. In public institutions cleanliness is only conspicuous by its absence. The patients are confined in wards which are foul; lie on beds which are saturated with foulness; the linen used is contaminated, and it is not to be wondered at that we should have periodical outbreaks of puerperal fever, and such a high mortality. Antiseptics by themselves cannot lower the mortality; but when antiseptics are made to embrace a complete change of linen, and thorough cleanliness all round is enforced, we have at once a lowering of mortality. This was illustrated long before the days of antiseptics, as may be seen by referring to a paper by Dr. Joseph Clarke, entitled, "Observations on the Puerperal Fevers," published in 1790. Clarke seeing the havoc wrought by puerperal fever, and the high mortality, with good judgment had his wards whitewashed; bedsteads and all the woodwork painted. Everything belonging to the bedding that it was possible to wash was scoured, and the remainder exposed for days to the open air, with the result that out of 960 women delivered, only three died. Dr. Clarke was on the right track when he laid down further suggestions, that the outfits of lying-in hospitals should be annually renewed, and that cleanliness should be scrupulously observed. We are glad to see that in modern lying-in hospitals they are depending not alone on antiseptics, but upon the rotation of wards, fresh bedding, and absolute cleanliness, which lies at the basis of all surgical treatment.

We have pleasure in publishing the report of the Preston Retreat for Women, Philadelphia, U.S.A., to prove how much can be done by cleanliness towards the extinction of puerperal diseases. Howard insisted in 1790 upon the rotation of wards, and we are pleased to see that Howard's idea is carried out in the year of grace 1889.

Dr. Price reported that during the year 1888 there were 184 deliveries in the Retreat. Of these patients sixty-nine were primaparas. There were 186 children born, including two sets of twins: nine of these infants were stillborn; 102 were males; eighty-four were females. There were thirteen forceps deliveries. Labour was induced in two cases in the eighth month. In one case a contracted pelvis, and in one the presence of a large uterine tumour. There have been no deaths of mothers in the Retreat for a period of nearly five years, furnishing a series of 540 deliveries without a death, the last death being from puerperal convulsions in a patient suffering from chronic Bright's disease, and who had had convulsions in five previous labours. Since this death there has not been a case of puerperal septicæmia in the institution. The great success attending the work of this maternity is dûe to the strict enforcement of the law of cleanliness. Everything and everybody in the house is clean and jealously kept so. This system was enforced by Dr. Goodell, and has been carried out on the lines laid down by him. The routine treatment of patients is as follows: the patient on entering the house is given a hot soap bath, dressed in clean underclothing, and given a clean bed in the waiting ward. If necessary, a laxative is given and the bowels kept soluble during her waiting period. Thereafter, until her confinement, she is obliged to take at least two hot soap baths per week and to wear clean clothes. She is allowed to do such light work about the house as the physician may deem advisable, and is encouraged to take as much open-air exercise as circumstances will permit. Every effort is made by the officers and employés of the institution to make it as cheerful and homelike as possible. When ready for the delivery room the patient is again given a hot soap bath and an enema and a vaginal injection of 1 to 2000 bichloride of mercury solution. She is clothed in a clean night-robe and drawers and placed upon a new clean delivery bed. Scrupulous cleanliness is observed in all manipulations of the patient, and after delivery a second vaginal injection is given, and a vaginal suppository of iodoform is introduced. The patient's person is carefully cleaned and all soiled clothing removed, the binder applied, a clean set of night clothes put on, and the patient placed in a new clean bed in the ward. All of the soiled articles are immediately removed from the delivery room, and a new bed made up for the next patient. The patients in the ward are carefully observed by the nurses, but no unnecessary handling or interferences indulged in. The patients remain in the ward until they are able to be up, when they are removed to the convalescent ward. As the ward is emptied, the beds are burned, and all the bedding most carefully cleansed. No soiled linen (as draw-sheets, diapers, napkins or other articles of clothing) is allowed to remain in the ward, but when soiled is immediately placed in a covered receptacle, and removed from the ward and building. No sponges, wash-rags or absorbent cotton are used in the house. Corrosive jute supplies the place of these articles, being clean, soft, remarkable absorbent and cheap; it is destroyed immediately after use. The pads used to absorb the lochia are also composed of jute, and are likewise destroyed after use. The beds in the wards are of new straw. All discharges from the delivery room are immediately burned. All bedding soiled beyond cleansing or contaminated by purulent or specific discharges is likewise burned. In short, every effort is made to keep the house perfectly pure and sweet. *The arrangement of the house permits of rotation in the use of the wards, so that a ward, once emptied, is not again used until three others have been filled. In the meantime it is most carefully and scrupulously*

cleaned and thrown open to the atmosphere. A similar system is pursued in the convalescent wards and delivery room. A few alterations in the building have very markedly increased the effectiveness of the institution and the comfort of its inmates. In the first place, the bath-room and water-closets have been removed from the building proper, and placed in the towers in the rear. The plumbing is as near perfect as modern sanitary science can make it. The verandahs have been enclosed in glass, forming large, light, airy corridors about the rear of the building, and furnishing a distinct circulating atmosphere between the house proper and the wards and the water-closets. The ventilation of the entire building is simply perfect. The capacity of the house at present is about fifty patients per month, and, when a few contemplated changes are made, the capacity will be doubled, and the institution rendered as nearly an ideal maternity hospital as is practicable.

The above results are admirable, and we trust that some of the methods will be copied. After years of suffering perfection may be reached at last. The antiseptic system has, so far as bichloride of mercury is concerned, something to answer for—viz., the deaths caused by it. Sins of commission must be put against the sins of omission on the part of those who believe in cold water. We cannot forget that Dr. Lucien Butte published in the *Nouvelles Archives d'Obstétrique et de Gynécologie* the notes of some twenty cases of puerperal diseases in which the employment of the *liqueur de Van Swieten* (a $\frac{1}{500}$ solution of the perchloride) was attended with fatal results. From the rapidity with which fatal intoxication took place in most of the patients, the characteristic salivation and gingivitis were absent, and in several the cause of death was not suspected until revealed at the *post-mortem* examination, the abdominal pain and diarrhœa being attributed to puerperal causes. The symptoms generally presented themselves within from twenty-four to forty-eight hours, and rapidly led on to collapse. The effects were more marked in patients of debilitated or cachectic constitutions, and lacerations of the cervix or perineum, or ulcerating surfaces, seemed to favour absorption to a marked degree. Perchloride in the strength of 1 to 2,000 is useless to kill germs, so that pure water may as well be used in Dr. Price's hospital.

Annotations.

"Forsan et hæc olim meminisse juvabit."

THE LATEST RESULTS OF THE PASTEUR INSTITUTE.

We shall continue to chronicle each month the deaths. (See p. 237, April, 1889.)

Case VI.—Ernest Bey, of Oissel, bitten December 13th. Treated from December 17th till January 6th at the Institute. Died of hydrophobia February 25th.

Case VII.—This case has a feature of its own, namely, that fourteen months elapsed since the bite. He was of course one of the people cured. Edward M——, æt. nine, of Levallirs-Perret, Boulevard de Villers, bitten January 31st, 1888, treated at the Institute the whole of the month of February. Died of hydrophobia 9th March, 1889.

THE TRAINING OF NURSES.

The training of nurses is open to very great improvement. We make this statement advisedly. Why do so many young women break down during the period of probation or pupilage? The answer is at once to be found in the long hours of duty, and the manual labour which they have to discharge. It is frequently urged that women are physically unfit for the position of the higher grade of doctor, but what shall we say of their physical powers in the position of nurses? The labour of nursing is more exhausting than in any other occupation. Pitiful appeals have been made as to the hours of labour in shops where young women are employed, but the shop girl's work is light in comparison with that of the nurse. At some institutions nurses are on duty from twelve to fourteen hours. Surely the time has come for some agitation to rectify such long hours of labour. We are calmly told that the doctrine of the survival of the fittest is the only one that can be entertained where nurses are concerned. The strongest survive, and the weakest go to the wall. We protest against this horrible doctrine, which has nothing in common with Christianity. There should be room and work even for the weakest.

THE MIDLAND VOLUNTEER MEDICAL ASSOCIATION.

We had the pleasure of being present at the Annual Mess of the Midland Volunteer Medical Association at Birmingham, on April 11th, and we can congratulate the volunteer surgeons of the Midlands on the excellent organisation they are building up, and on their *esprit de corps*. The association consists of forty-eight members, who are brought into touch with one another by correspondence, by manœuvres, and, not least, by social intercourse at an annual dinner. The ideas taken up by the association are to create amongst the volunteer medical officers a spirit of action so as to bring the ambulance of each regiment into a state of efficiency, to dispel the prevailing notions that the volunteer surgeon is only a dispenser of medicines, and to prove to officers commanding that by proper medical administration and by the help of stretcher-bearers the efficiency of each regiment must be increased. By medical examination the volunteer surgeons weed out the inefficients who are in the fighting line; and at all manœuvres and long marches the ambulance has proved itself of the greatest possible service. It does not require any argument to prove that in case of service the ambulance would be essential for the efficient working of a corps. The Midland regiments are very fortunate indeed in having on their strength such men as Surgeon-Majors Morgan, Manby, Acting-Surgeon Freer, who have deve-

loped the ambulance at great personal sacrifice and expense, providing stretchers, water bottles, haversacks, field panniers, ambulance waggons, and material of the best kind, without encroaching on the funds of their corps, besides giving their time and services in the instruction of the bearers. At Wolverhampton Surgeon-Major Maunby has organised an ambulance, collecting over £240 for the purchase of material. The surgeon of a volunteer regiment stands in a somewhat different relation to that of the other officers. The combatant officer turns from his own profession to learn another one, but the volunteer surgeon, though he has to learn some drill, is still carrying on his profession when he goes into camp. He thus gives to a regiment a great deal more than any other officer, and a full recognition of the value of his services is received from only a few regiments. In some of the northern regiments this recognition is made by not allowing the surgeon to pay his expenses in camp, the commanding officers feeling that the surgeon has not only left his practice, but that he is still practising his profession; while he is earning at the same time a capitation for the regiment, and adding to its efficiency. The Midland Volunteer Medical Association owes very much of its success to the energy of Acting-Surgeon Freer, who as secretary has to organise, and really to do all the work. We commend to the notice of other districts the organisation existing in the midlands.

THE BUYING OF HOSPITAL APPOINTMENTS.

The purchase of hospital appointments may seem strange to English surgeons. It is a custom which prevails in Ireland, and which still finds favour in the country. Sums varying from £800 to £1,000 have been given for an appointment as hospital surgeon, though no salary is attached to the position. Why should a hospital appointment be worth this position? Simply because only through hospital appointments could the surgeon obtain recognition. By means of the hospital he was advertised; by means of the hospital, surgical skill was acquired, and virtually over the bodies of the poor the surgeon rose to eminence, when he could touch the pockets of the rich, and recoup himself for the £1,000 expended. The purchase of the appointment is much the same as the purchase of a practice in England. Occasionally incompetent men by means of money obtained the rank of hospital surgeon, but as a rule the Irish system has not been such a very immoral one as some critics would make out. In England incompetent men have bought practices, and do so still, but we do not see that the medical press takes any notice of the custom, or that it condems it.

FEES OF MEDICAL WITNESSES AT ASSIZE COURTS.

We published some time back a protest drawn up by the Wigan Medical Society, against the fees payable to medical witnesses in criminal cases. The subject is again coming to the front, and we can only repeat what we then said on the injustice of the present scale of fees. One guinea a day, with railway fare, is an inadequate fee for a medical witness. The interests of justice are not served by this scale of remuneration, and we do not wonder at the statement which has been made in one of our daily papers by a medical man, that if he witnessed an accident, and thought it likely he would have to go to the assizes, he would slip away. This is an extreme way of putting one individual's sense of the injustice. Medical men cannot afford to injure themselves even for the general good. The profession is always ready to render aid in any emergency, without any fee; but when the emergency is over, an act of kindness may involve a further pecuniary loss. The medical man may well hesitate, and doubt whether he can be expected to sacrifice his own interests any further. We trust that the present agitation may result in a thorough revision of the scale of fees.

MEDICAL LEGISLATION IN TENNESSEE.

We learn that there is before the Legislature a Bill to regulate the practice of medicine in the State of Tennessee. The Bill is very stringent in its provisions, and travelling doctors or peddlers of drug nostrums or patent medicines are required by its terms to pay $100 a month to the State. It provides for a State Board of Medical Examiners, who shall issue certificates or licenses to practice, either upon examination or upon proof that the applicant was a practising physician prior to the passage of the act. These certificates shall be recorded in the office of the county court clerk. Practising medicine without such a certificate shall subject the offender to a fine of $100 for the first offence, and $200 for each subsequent offence. The same penalty is attached to "any itinerent vendor of any drug, nostrum, ointment or application of any kind intended for the treatment of disease or injury, or who may by writing, printing or other methods, profess to cure or treat disease or deformity by any drug, nostrum, manipulation or other expedient," who does not pay to the Board of Examiners $100 a month for such privileges.

PAUPERS *AND* PAUPERS.

"The methods of relief which are available for the poor may be broadly divided into two classes: Poor-law infirmaries and charitably maintained hospitals. As they are at present conducted, there is no strict line of demarcation between the two. For all practical purposes they are both supported by one and the same class, and that class is entirely distinct from those by whom they are used. The general hospitals are as much maintained by the money of the wealthy as are the Poor-law infirmaries. The only real difference is that in the former case the wealthy tax themselves, whereas in the latter they are taxed by the State. *To hold, therefore, that a man is degraded to the level of pauperism if he goes to a poor-law infirmary, whilst he retains his full self-respect and independence if he goes to a general hospital, is sheer nonsense.*"

We are pleased to note the above paragraph in the

Hospital; it is a view of the question which for years we have been urging. It has given great offence to some to class the working men who accept gratuitous advice at the voluntary hospital with the poor who frequent the Poor-law dispensaries. The State-aided infirmary is the proper place for the poor; there should be no stigma attached to them for seeking advice for which they have in their time paid rates. There should be a stigma on the working man who cadges on the charities.

BRITISH MEDICAL ASSOCIATION.

The fifty-seventh annual meeting of the British Medical Association will be held at Leeds, on Tuesday, Wednesday, Thursday, and Friday, August 13th, 14th, 15th, and 16th, 1889. The profession in Leeds are trying to organize a large meeting, and have contributed a large sum of money for the expenses of entertainment. The president-elect is G. G. Wheelhouse, F.R.C.S., J.P., Consulting-Surgeon Leeds General Infirmary. As Mr. Wheelhouse claims to be a general practitioner, we must emphasize the value of his election. The address in medicine will be delivered by Dr. Hughlings Jackson; the address in surgery by T. Pridgin Teale, F.R.S., F.R.C.S.

An address in psychology will be delivered by Sir J. Crichton Browne, M.D., LL.D., F.R.S., Lord Chancellor's Visitor in Lunacy, London.

A. Medicine.—*President*, Thomas Clifford Allbutt, M.D., F.R.S. *Vice-Presidents*, Charles Parsons, M.D.; Robert Saundby, M.D. *Honorary Secretaries*, Alfred George Barrs, M.D., 22, Park Place, Leeds; Theodore Dyke Acland, M.D., 7, Brook Street, Grosvenor Square, W.

B. Surgery. — *President*, Thomas Richard Jessop, F.R.C.S. *Vice-Presidents*, Edward Atkinson, M.R.C.S.; Arthur F. McGill, F.R.C.S.; Henry Morris, F.R.C.S. *Honorary Secretaries*, Arthur W. Mayo Robson, F.R.C.S., Hillary Place, Woodhouse Lane, Leeds; Edward Ward, M.B., 22, Park Place, Leeds.

C. Obstetric Medicine and Gynæcology.—*President*, Charles J. Cullingworth, M.D. *Vice-Presidents*, James Braithwaite, M.D.; J. W. Byers, M.D. *Honorary Secretaries*, F. Hall, M.D., St. Mark's House, Leeds; Peter Horrocks, M.D., 9, St. Thomas's Street, S.E.

D. Public Medicine.—*President*, John Edwin Eddison, M.D. *Vice-Presidents*, George Goldie, L.R.C.P. Edin.; Shirley F. Murphy, M.R.C.S. *Honorary Secretaries*, George Eastes, M.B., 35, Gloucester Place, Hyde Park, W.; Arthur Stopford Underhill, M.D., Great Bridge, Tipton, Staffs.

E. Psychology.—*President*, D. Hack Tuke, F.R.C.P., LL.D. *Vice-Presidents*, W. Bevan Lewis, L.R.C.P.; Ringrose Atkins, M.D. *Honorary Secretartes*, John Greig McDowall, M.D., Bethlem Royal Hospital, S.E.

F. Pathology and Physiology.—*President*, Joseph Coats, M.D. *Vice-Presidents*, Thomas Churton, M.D.; De Burgh Birch, M.D. *Honorary Secretaries*, Ernest Henry Jacob, M.D., 12, Park Street, Leeds; T. Wardrop Griffiths, M.B., 23, Park Square, Leeds.

G. Ophthalmology. — *President*, George Anderson Critchett, F.R.C.S. Edin. *Vice-Presidents*, John Albert Nunneley, M.B.; George A. Berry, M.B. *Honorary Secretaries*, Gustavus Hartridge, F.R.C.S., 65, Green Street, Grosvenor Square, W.; R. N. Hartley, M.B., 29, Blenheim Terrace, Leeds.

H. Diseases of Children. — *President*, Thomas Scattergood, M.R.C.S. *Vice-Presidents*, Richard Favell, M.R.C.S.; A. H. Carter, M.D. *Honorary Secretaries*, Walter Henry Brown, M.R.C.S., 19, Queen Street, Leeds; Angel Money, M.D., 24, Harley Street, Cavendish Square, W.

I. Laryngology.—*President*, Henry T. Butlin, F.R.C.S. *Vice-Presidents*, Francis de Havilland Hall, M.D.; Richard A. Hayes, M.D. *Honorary Secretaries*, G. M. Macdonald, M.D., 47, Queen Anne Street, Cavendish Square, W.; Barclay J. Baron, M.D., 16, Whiteladies Road, Bristol.

J. Otology.—*President*, George P. Field, M.R.C.S. *Vice-Presidents*, Frederick Morrish Pierce, M.D.; Henry B. Hewetson, M.R.C.S *Honorary Secretaries*, Adolph Bronner, M.D., 33, Manor Row, Bradford; G. William Hill, M.B., 27. Cornwall Road, W.

Honorary Local Secretaries, Charles J. Wright, M.R.C.S., Lynton Villa, Virginia Road, Leeds; Charles M. Chadwick, M.D., 3, Park Square, Leeds; G. Herbert Rowe, M.R.C.S., Hillary Place, Leeds.

Programme of Proceedings.

Tuesday, August 13th, 1889.

9.30 a.m.—Meeting of 1888-89 Council.

11.30 a.m.—First General Meeting. Report of Council. Reports of Committees; and other business.

4 p.m.—Service in Parish Church. Sermon by the Right Rev. the Lord Bishop of Ripon.

8.30 p.m.—Adjourned General Meeting from 11.30 a.m. President's Address.

Wednesdays, August 14th, 1889.

9.30 a.m.—Meeting of 1889-90 Council.

10 a.m. to 2 p.m.—Sectional Meetings.

3 p.m.—Second General Meeting. Address in Medicine by J. Hughlings Jackson, M.D., LL.D., F.R.S.

4.30 to 6 p.m.—Afternoon Reception at the Yorkshire College by the President, Council, and Senate of the College.

8-30 p.m.—*Conversazione* by the President of the Association and Local Executive Committee in the Art Gallery and Municipal Buildings.

Thursday, August 15th, 1889.

9.30 a.m.—Meeting of the Council.

10 a.m. to 2 p.m.—Sectional Meetings.

3 p.m.—Third General Meeting. Address in Surgery by T. Pridgin Teale, M.A., F.R.S., F.R.C.S.

4.30 to 6 p.m.—Probable visit to the new W.R. Asylum at Menston.

7 p.m.—Public Dinner of the Association in the Town Hall.

Friday, August 16th, 1889.

10.30 a.m. to 1.30 p.m.—Sectional Meetings.

3 p.m.—Concluding General Meeting. Address in Psychology by Sir James Crichton Browne, M.D., F.R.S.

4.30 to 6 p.m.—Garden Party at the W.R. Asylum, Wakefield.

8.30 p.m.—Reception and Ball by the Mayor of Leeds in the Town Hall.

Saturday, August 17th, 1889.

Excursions.

DEATH OF DR. JOSEPH ROGERS.

We regret to announce the death of Dr. Joseph Rogers, Chairman of the Poor-Law Medical Officers' Association, a man of indefatigable energy in the cause he had so much at heart—viz., that of the Poor-law service. He was almost the last of a band distinguished by their zeal and unselfishness, who, some thirty years ago, took up the cause of the poor, and who fought against oppression and injustice with an energy unknown in these degenerate days. The Poor-law medical officers of to-day owe their positions to Drs. Griffin, Enslie, Fowler, Rogers, and others, who have since gone over to the majority. There is a difference between the old Strand workhouse to which Dr. Rogers was appointed at a salary of £50 a year, *finding all medicines and appliances*, and the modern workhouse hospital, as the one recently opened at Birmingham with its medical staff, etc. Dr. Rogers lived to see the Poor-law system placed, if not on a satisfactory basis, still on one that promises to be satisfactory in the future.

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. Kesteven, M.D.

A Novel Cure for Constipation (*Medical Press*, April 3rd, 1889).—The relief of obstinate constipation is often a matter of considerable difficulty that any plan, at once simple and permanent, of attaining the desired end is likely to secure general attention. In this connection Dr. Clement Cleveland, of New York, claims that he has obtained most gratifying results from forcible dilitation of the sphincter and muscle, which, according to a communication in the *New York Medical Record*, he has now performed ten times, in all successfully. The theoretical grounds on which the relief thus afforded is explained are that fæcal matter passing from the colon into the rectum arouses in the latter the conjoined muscular action by which its expulsion is to be secured. But in cases of long-standing constipation the nerves of the rectum, distended by hard, dry fæces, are blunted in sensibility, and the contractile power of its muscular fibres is consequently much enfeebled, so that they are incompetent, even when aided by the expiratory muscles. to overcome the resistance of the sphincter, which thus acts as a barrier to the hardened masses. These latter, by over-stimulating it to contract, prevent it from grasping the material packed close against it, and so downward movement of the scybala is impossible. When, however, the muscular band has been forcibly stretched, it offers oniy a passive resistance to the fæces, but still continues to check involuntary defæcation when not aided by the expulsive force of the respiratory muscles. The proposed operation seems not unlikely to prove beneficial in certain selected cases, and it may possibly have a future before it.

A case of Death from Anæmia due to the Ankylostomum Duodenale (read before the Medical Society of Queensland). By James B. Hogg, L.R.C.P. et R.C.S., Edin., Assistant Medical Superintendent Woogaroo Lunatic Asylum, Goodna (*Australasian Medical Gazette*, February 7th, 1889).—P. C. C.——, æt. thirty-six, single, labourer, native of Denmark, was admitted to the asylum from Cleremont in December, 1878. He was suffering from mania which gradually passed into secondary dementia. He was quite unable to give any account of himself, and never made any complaints as to his health. He was very dirty in his habits, passing his urine and fæces into his clothes, filling his ears and nose with pebbles, threading bits of wire through his nails, etc. He habitually swallowed large quantities of stones, and on one occasion when he had to be closely watched in order that we might recover two keys which he had snatched from ayslum attendants, we found in his motions, besides, stones, etc., the two keys, a penknife, and the bowl of a pipe with a three quarters of an inch of stem. On 15th June, 1885, his feet and ankles were found to be œdematous, but his heart seemed right and his urine was free from albumen. On 21st September, 1885, he is reported "well again." On 10th January, 1886, his feet, legs, and eyelids were noticed to be œdematous, and his urine contained a trace of albumen. By 10th March he had again recovered. On 15th October, 1888, he was seen to be thinner and paler, and by the 5th November he had become very anæmic and generally dropsical. His urine was clear, watery, sp. gr.: 1.005 acid, and contained about one-twelfth of albumen. Tube casts were not looked for. Thenceforward he lay in a condition of gradually deepening anæmia and anasarca, dying on the 8th December, 1888. A *post-mortem* examination was made. In the jejunum were thirty or forty minute worms, each about one-third of an inch long, adherent by one extremity to the mucous membrane. Under the microscope these worms were recognised as specimens of the Ankylostomum duodenale. This worm is the cause of a form of anæmia, due to the loss of blood abstracted from the system by the worm which acts like leeches. This worm gains admittance to its host through food or drink.

Notes on some Anti-Vaccination Fallacies. By Arthur F. Hopkirk, M.D. (*Medical Press*, April 3rd, 1888).—Dr. Hopkirk categorically answers the fallacies by facts. We quote from the latter, apart from the former, as sufficient refutation thereof. Statistics have established the fact that in the previous century one-tenth of mankind died from small-pox, and another tenth was permanently injured by that disease. Since the introduction of vaccination, the mortality from small-pox has been reduced to a minimum. Varioloid is now-a-days much more frequent, and even variola runs a milder course. From varioloid alone healthy adults hardly ever die. The danger of the transfer of syphilis, or other diseases, by vaccination may be reduced to such a minimum that the benefits of vaccination infinitely outweigh any possible injurious effects. Of 2,800,000 vaccinations performed in Germany in 1883, not a single case of transmitted syphilis, or other illness, has been observed. Since 1875, when compulsory vaccination was enforced, not one single German soldier had died of small-pox, but the mortality from that disease has remained very high both in the French and Austrian armies. In 1886, the small-pox death-rate per 100,000 was, in Berlin, 0.07; in Hamburg, 3.58; in Munich, 0.75; in Dresden, 0.0; in Breslau, 0.0; in London, 0.6; in Vienna, 26.15; in St. Petersburg, 15.30; in Prague, 55.49; in Buda Pesth, 368.7; in Marseilles, 543.3; in the German army, 0.0; in the Austrian and French armies, 7.9 each: total small-pox mortality in Germany, 155; in Marseilles, 2,051!!!!! It being thus an incontrovertible fact that in Germany, the only thoroughly vaccinated country in the world, small-pox has ceased to be a scourge, need one be surprised that the opposition to compulsory vaccination in that highly-educated land is as minimal as the mortality from small-pox?

Charcot on Suspension in Locomotor Ataxia (*Medical Press*, April 3rd 1889).—Dr. Prendergast, writing from Paris, made the following statement on the above:—Your Paris Correspondent, who generally gives such a precise and faithful *resumé* of French medical progress, has I fear this time, with all respect, allowed his enthusiasm to somewhat eclipse his accuracy. In your issue of March 20, *à propos* of this method and the "most extraordinary success" attending it at the Salpétrière, he says: "Out of eighteen cases, some of which were very aggravated, only four were not benefited, and of these even the fault lay in the patients themselves, in the fact that they did not persevere in the treatment. All the others were more or less relieved, and some were *completely cured*. . . . It seems that by hanging a man up to the ceiling once a day until he is—not dead—but *cured*, that insidious and until lately incurable disease can be conquered. Such is the testimony of such a great professor as Charcot, and certainly his opinion ought to carry weight." Now without any doubt the testimony of Professor Charcot carries the greatest possible weight; but unfortunately this is not Professor Charcot's testimony. On referring to my notes of his *séance* of January 15, I find he very cautiously confined his praise of the method, so far as he had carried it out, to the word *amelioration*. He pointed to the amelioration—in some cases marked—in, for instance, the following prominent symptoms: Incoordination, the sign of Romberg, the sexual impotency, the lightning pains, the vesical troubles, &c.; and he remarked that this was certainly a great deal, and should commend the treatment for trial to any practitioner having a poor patient so afflicted, but he studiously avoided the word cured. Lest there should be any conflict of testimony, however, I showed the distinguished *maître* your correspondent's lines a day or so ago in the course of conversation, and Professor Charcot now authorises me to say that he does not consider any of the eighteen patients "cured," much less "completely cured"; moreover, the Professor added he has little hope that any such method will ever procure the cure, in the ordinary acceptation of the term, of locomotor ataxia.

Massage in Gynæcological Practice (*Medical Press*, April 3rd, 1889).—At a meeting of the British Gynæcological Society (Mar. 27th),

Dr. Macnaughton Jones, in reply to criticism from a paper that he had read, said that he had never used internal massage in certain pelvic conditions, because he was afraid of the danger of such a course, nor, on the other hand, had he used such strong language in condemnation of internal massage as had been used that evening. He entirely differed from the President when he implied there was an analogy between the use of the speculum and internal massage. He also took exception to the present form of internal massage as practised by Jackson and others. He had endeavoured to treat the subject from a much wider point of view than what was done in London houses and London hospitals. Looked at in an unprejudiced light, it could not be regarded as quackery. He did not agree either with Dr. Bantock when he stigmatised the physiological results of massage as "high falutin." He took a broad view of massage, and he maintained that it was only by taking the physiological effects of the process into account and applying their knowledge to the pelvic viscera, that they could hope to arrive at good results in the pelvic region. The failure of massage when applied to unsuitable cases was not a fair argument against it. He recapitulated the special gynæcological cases in which he had stated he found massage of service. He believed the Weir-Mitchell treatment had been much abused. He had been struck with the remark that costiveness was not a gynæcological trouble. He said that no one who had given much attention to gynæcological cases would dispute that it was a frequently associated trouble. He had been grievously disappointed at the discussion. He had purposely taken a broad view, and he had expected a discussion on similar lines. He had not intended to write a paper on the abuse of massage, but he might have done so from the turn the discussion had taken. It was the indiscriminate and often barbarous use of massage to which he had referred. That it was that had brought it into disrepute. So far as he was at present able to say, he did not doubt that the scientific application of *internal* massage might be followed by the best results, but as at present applied, it might be followed by far more injurious results than the benefits that accrue from it. We quote the editorial comments upon this discussion :—

"Whether he intended it or not, his paper certainly contains the materia for a formidable indictment, and it is not surprising that advantage was taken of the opportunity to put into words, feelings which have long been current in reference to the questionable practices which are carried on in London and elsewhere under the specious garb of 'uterine' and other varieties of massage. When one hears the reproach made against itinerant masseurs and masseuses that they earn sums which an 'M.B. of London or an M.R.C.S.' cannot hope to gain until after years of practice, it is difficult to avoid the impression that the facility with which these adepts in a now fashionable method of treatment earn a generous livelihood is not altogether foreign to the outcry against the abuse of massage. We will willingly acquit the author of the paper of any intention to decry a treatment of which he has so eloquently described the advantages, an eloquence which, by the way, appears to have been largely thrown away upon many of the operating abdominal surgeons who were present. It may be alleged that the undisguised contempt with which the latter regard massage savours of jealousy, that so many cases admirably suited to reflect credit upon the surgeon who undertakes their operative cure should be allowed to gravitate elsewhere. It must be admitted, however, by impartial observers that the main arguments of those who see in massage merely a means of 'sweating' persons with thin bodies and fat purses, are based upon instances in which the method has been resorted to, or recommended, without sufficient cause, or in spite of what, according to them, ought to have been considered to be contra-indications. Whatever the value of massage may be, it is obvious that it is not to be calculated from instances in which it had been employed *mal à propos*. There is, however, one point upon which both parties are agreed, and that is as to the harm done by sanctioning the carrying out of this or any other method of treatment by persons whose only title to practise in the particular department has been the payment of a few pounds to some speculative lecturer or *soi-disant* teacher of the art. The number of ladies and gentleman who now adorn their patronyms with the proud and lucrative designation of professors of the art and mystery of massage is legion. Quackery is not this or that treatment, but the method in which it is carried out, and for this reason it is sometimes possible to point to cases in which even persons within the sacred fold of the profession have been guilty of practices which are perilously near the boundary line of quackery."

Recovery from Extensive Compound Fracture of the Skull. T. Carson Fisher, M.D., Ch. M., Sydney (*The Australasian Medical Gazette*, February, 1889).—E. K——, æt. thirty years, received a blow on the head from a glass tumbler that had been thrown at him. On admission to the Sydney Hospital, May, 1888, he was conscious, but aphasic. The pupils were equal, and reacted to light. Pulse 105; no paralysis. On the left side of the head was a curved wound two and a half inches long, transverse in direction, about three inches above the tip of the ear. "The scalp was cut through, and at the bottom of the wound several loose portions of bone were felt, corresponding to the extent of the wound. There was a space about one-third of an inch wide between the edges of bone, in which the pulsation of the brain could be seen and felt. When the loose fragments of bone were removed, there was visible an uncovered area of dura mater, of irregular oval shape, about two and a half inches long, one inch in the transverse and vertical diameter. Bleeding from the arteries of the scalp was checked by pressure, while three-clip forceps included in their grasp the bone and some divided meningeal branches. A moist sponge, with slight pressure, was put over the wound." When bleeding had ceased, the edges of the wound were united by hare-lip pins. There were no marked symptoms of cerebral lesion, beyond aphasia of a peculiar type. He understands what is said to him, and answered in monosyllables, but cannot form a sentence. He seems to have command of ideas, but to have difficulty in articulating any beyond the simplest single words. His intelligence was unimpaired. The tongue deviated slightly to the left. He could write, but in a shaky hand. The case progressed favourably, and on July 13th he was made an out-patient.

"This case illustrates the fact that extensive fractures of the skull, with little or no injury to the brain or its membranes, allow of recovery without dangerous symptoms. It shows also Nature's method of repair. The large hole in this man's skull was filled by tissue so firm that it formed a covering nearly as effectual as bone itself. The site of the brain lesion is of some interest. The motor aphasia was the first and prominent symptom, and preceded by a few days the facial paralysis, which was incomplete, the upper part of the face being little affected, as is usual in lesions of the motor path between the cortex and the nucleus of origin of the facial nerve. The centres for movements of the mouth, lips, and face, lie grouped closely together about the lower end of the fissure of Rolando, and this area was crossed by the wound. The form of aphasia noticed in this case is termed aphemia by Bastian, who thinks that the lesion causing it is in the sub-cortical part of Broca's convolution, *i.e.*, involving the internuncial fibres from the left speech centre (glosso-kinetic centre, as he terms it) to the bulbar-motor centre."

Paralysis after Compound Fracture of the Skull, Treated by Trephining—Recovery. Reported by Dr. Marwood, Resident Surgeon, Geelong Hospital, Victoria (*Australasian Medical Gazette*, February, 1889).—J. J. K——, æt. one and a half years, the day previous to admission (November 15th, 1888), fell out of bed, striking his head against a small iron cot. His mother brought him to the Geelong Hospital, stating he had fits! ! (clonic spasms ?) ever since. Dr. Hope and I, on examination, found a small punctured fracture over the right frontal bone. The patient had left hemiplegia and right pupil dilated; breathing stertorous, and pulse small. Trephining was decided upon, which was performed by Dr. Hope. A portion of the inner table, about the size of a sixpence, was found to be detached and pressing on the brain. This was elevated, the wound dressed antiseptically, and the child put to bed. Within twenty minutes after the operation all signs of paralysis had disappeared. The temperature in the evening was 101.6. From that time the child made steady recovery, and was discharged three weeks after, with the wound almost completely healed. The chief points of interest are: The small size of the fracture, causing such extensive paralysis; and the immediate improvement after the operation.

Relation of the Age of Parents to the Vitality of Infants (*L'Union Médicale*, April 2nd, 1889).—A Hungarian *savant* has arrived at the following conclusions from the study of 25,000 cases: The issue of very young parents have feeble constitutions; the children of old parents are in a like category; the most robust children are those born of a mother under thirty years of age and a father over thirty-five.

Treatment of Phthisis with Tannin (*L'Union Médicale*, April 2nd, 1889).—Dr. E. Howzé, of the Hospital St. Jean, Brussels, has for the last eight months treated all his phthisical patients with tannin, with excellent results in all stages of the disease, especially where cavities had existed. The dose administered has been seventy-five centigrammes (equal to about ten grains in English), repeated three times a day. At the end of a few days, the expectoration and night sweats diminish, and in most cases the appetite is improved. The physical signs are reported to present an equal amelioration, the moist râles giving place to a dry rhoncus. Hectic declines, while the patient gains strength and increases in weight.

II.—SELECTIONS FROM CONTINENTAL MEDICAL JOURNALS.

BY G. F. CADOGAN-MASTERMAN, M.D.

Paradental Epithelioma. Dr. Polaillon (*L'Union Médicale*).—A. S——, æt. fifty-three, a tutor, was admitted to the hospital *de la Pitié* on October 19th, 1888, for the removal of a tumour growing from the right inferior maxilla. At the beginning of the year 1883 the patient noticed a growth, about the size of a haricot bean, on the outer margin of the right jaw, which had been several times the site of a gum-boil. The teeth were all in very bad condition, but the patient's general health was excellent. Beyond rubbing the little tumour with iodine ointment, nothing was done, and its condition seemed stationary until the end of the year, when severe pain, extending from the cheek and down the neck, suddenly set in; it lasted for twenty-four hours. Mastication and deglutition were difficult, and the growth rapidly enlarged. By October, 1887, it was as large as an apple, and extremely painful, and at the time of the patient's entry into the hospital it had reached the size of the fœtal head. Some vegetations had also sprung from the adjoining gum, sphacelated and sloughed away, leaving an evil-smelling and bleeding cavity, greatly to the sufferer's distress. Externally, the tumour extended from the right ear to the median line of the lower jaw, and reached nearly to the middle of the neck, the surface smooth, the skin over it very thin, but healthy. To the touch some portions were as hard as wood, others somewhat elastic, and near the chin it felt and crackled exactly like dry parchment. Handling it gave the patient great pain. Within the mouth, in place of the gum on the right side, there were two vascular growths as large as a nut, dark purple in colour, and bleeding at the lightest touch. The molar teeth had disappeared; the bicuspids remained, but were greatly displaced. It was clear that the growth had commenced within the horizontal portion of the inferior maxilla, had distended it into a thin bony shell, and then expanded between the mucous membrane and the muscles of the cheek. The two outgrowths were probably pushed through the sockets of the lost molars. It was diagnosed as an osteo-sarcoma, but the subsequent microscopic examination showed that this was a mistake.

The operation was performed on the 25th of October, 1888. Chloroform was administered, and a curved incision made from the lobe of the right ear to the commissure of the lips, a second curved incision lower down isolated the thin integument covering the most prominent part of the tumour. Then, without opening the buccal cavity, this was carefully separated above and below from the soft parts, and the facial artery was ligatured in two places, and divided between them. The lower lip was incised, and separated from the bone, which was cut through with a chain-saw on the median line. The healthy buccal mucous membrane was easily separated from the surface of the tumour. The masseter, internal pterygoid and temporal muscles were then divided, and a simple twist at once disarticulated the jaw, and brought away the whole of the growth with it. The divided mucous membrane of the floor of the mouth was carefully sewn with silk to that of the cheek, so as to completely shut off the cavity of the mouth from the wound. A few vessels were also ligatured, and the incision in the cheek closed, after the insertion of two drainage tubes, with silver wire sutures, and the whole covered with antiseptic dressings. Healing went on very rapidly. The mucous membrane united at once. Two or three suppurating points in the external wound gave exit to the arterial sutures, and eventually to a fragment of bone, but were soundly closed by the 11th of December, when the patient left the hospital for a convalescent home. One great advantage of completely isolating the oral cavity from the wound was that it facilitated the taking of food, and that not a drop of pus ever mixed with it. The patient is now perfectly well; articulation is not in the least interfered with; and the power of masticating is better than one would expect. A firm fibrous growth has taken the place of the lost half of the jaw, and after a time a dental plate will be fitted there. The tumour was found to be epitheliomatous in structure, mainly covered externally with the wonderfully expanded bone of the lower jaw, containing internally white rounded masses, some extremely hard, others softened, and undergoing cystic degeneration.

Etiology and Treatment of Diabetes. Dr. Cantani (Naples).—Diabetes, the author regards as a general disease with special localisation in the chylopoietic viscera. One secondary result of the disease is diminished excretion of carbonic acid, from the lessened oxidation of the carbo-hydrates of the food; and he considers that the excessive use of fecular and saccharine substances is its cause, their constant digestion setting up a train of unnatural phenomena in the system which is fatal to healthy assimilation. It is only in very rare instances that disturbance of the nervous system gives rise to it. Having treated more than a thousand diabetics, he could affirm that the most important point was the absolute deprivation of meat; the least transgression of this rule led to the return of the glycosuria. Milk rendered alkaline by the addition of carbonate of potash or soda, an albuminous regimen with cream or butter, are to be advised. Dr. Renzi states that when he was practising in Geneva, where meat is very largely eaten, he scarcely saw two or three cases in a year; but in Naples, where the people live chiefly upon grain and pulse, he sees from forty to fifty in the same period. A case is quoted by Dr. Baccelli of a young man who suffered a concussion of the brain, and afterwards became diabetic. He died eventually, and the necrobiotic point was found in the centre of the *pons Varolii*. In this instance, the disease was clearly due to nervous influence.

Treatment of Hydatid Cysts. Dr. Baccelli (Rome).—By means of a hypodermic syringe, carefully sterilised, and used with all aseptic precautions, withdraw about two drachms of the cystic fluid, and replace it by an equal volume of the liq. hydragrari perchloridi, P.B. The author directs ten grammes, containing one to five centigrammes of the salt. This treatment is extremely simple, perfectly safe, and gives excellent results (*Giornale delle Scienze Mediche Roma*).

Attacks of Fever due to a Stricture of the Urethra. Dr. Dubuc (*L'Union Médicale*).—The phenomenon of rigors, followed by a rapid pulse and high temperature after mechanichal dilatation of the urethra, is familiar enough under the name of "cathether fever;" but Dr. Dubuc has seen several examples of a similar condition, and of same duration, due to the irritation caused by the passage of the urine alone through an old and tight stricture. He selects two cases as illustrations: The first is that of a man now æt. seventy-six, who in his fortieth year was treated for the first time for bulbar stricture by gradual dilatation. When No. 14 (French) could be passed, the treatment was discontinued, but he was directed to introduce a bougie of that calibre at least once a week for some months afterwards. Eighteen years later he consulted the author about his old trouble, which was relieved in the same way and to the same extent as before, it being found impossible to dilate the canal to a greater extent. He was seen and treated occasionally during the succeeding three years, and then lost sight of, and he seems himself to have been so well satisfied with his condition that the hebdomadal bougie was neglected, and at length forgotten. In October, 1876, Dr. Dubuc was summoned to see him in the country, and found him in very bad condition. He had been staying in a somewhat marshy district, and had had a series of attacks resembling tertian ague, only the stages were neither regular nor well-defined. There was always severe shivering, followed by the usual hot stage, but no sweating, only a little moisture on the skin. His local medical attendant, who had been told nothing of his urinary troubles, treated him with quinine, looking upon the case as one of ill-defined paludal fever, and finding that he made no progress, recommended change of air. It then occurred to the patient himself that the mischief was possibly the Nemesis of his own neglect, especially as the urethra had by that time contracted so much that the urine could only be voided *guttatim*, and was constantly dribbling away. He had lost strength and appetite, become shrivelled and cadaverous, his mouth was always dry, the tongue covered with brown fur, and the saliva distinctly acid, and the attacks of fever recurred twice nearly every twenty-four hours. The urine was ammoniacal, very fœtid, and thick with pus and mucus.

He was advised to return to Paris, and the next day a No. 6 (French, about No. 2 English) gum-elastic catheter was passed after some difficulties and tied in. The quinine was repeated and milk diet ordered. So soon as the next morning there was evident improvement in all respects. No. 9 was then introduced and the bladder washed out daily. By the fifth day the feverishness had disappeared, the appetite returned and the vesical troubles so far reduced that the patient had need to micturate only every three hours, and the bladder could be emptied completely. The dilatation was pushed to No. 18, and then the patient was left to his own devices, but with the injunction to pass a No. 16 at least once a week. All went on well for a time, and then immunity begat the old carelessness with the result in 1883 of an attack of cystitis. The stricture had then retroceded to the diameter of No. 11, but in a week No. 21 could be passed after the usual slow gradation. The inflammed bladder was washed out with a solution of boracic acid, with unsatisfactory result, then with one of nitrate of silver (1 to 1200), which after a few repetitions was quite successful. And the patient, having at length learnt that his condition was really in his own hands, is now in his seventy-sixth year, a fairly healthy old man both generally and locally. (2) The second case has many points of similarity, the patient was first treated for stricture in his forty-fourth year by gradual dilatation, and was enjoined to afterwards pass a catheter regularly, not only to prevent recontraction but to thoroughly empty an irritable bladder with enlarged prostate. The injunction was disregarded, and five years later he came into the hands of the author, who performed internal urethotomy with Maisonneuve's

instrument. There was at the time of the operation the half of a broken catheter in the bladder, and which was passed spontaneously immediately afterwards. In December, 1887, he had several sharp attacks of fever from an unexplained cause, but from that time until the following spring his general health continued excellent, and the author saw nothing of him until the 26th of March, 1888, when he was sent for to meet his usual medical attendant in consultation. The day before, whilst on a railway journey, he had been taken suddenly ill, vomited, and was with difficulty got to his daughter's house and in bed when fever set in. The cause was at once recognised, and quinine had been prescribed before the consultation. There was found on joint examination a long, tight stricture, admitting a No. 11 with difficulty, purulent and highly ammoniacal urine, acute cystitis and consecutive fever. An ounce of castor oil was given, four grains of quinine every four hours, plenty of hot tea with a little rum, and large poultices over the pubes and loins. By the 27th, the high temperature had fallen to the normal point, pain had disappeared, and the skin was acting well. The patient was put on milk diet, and the quinine reduced to ten grains in the twenty-four hours. The next day a No. 11 (French) catheter was introduced with difficulty, and was tied in after the bladder had been well washed out with a solution of boracic acid. Every day a catheter of two mm. greater diameter than the preceding was left in, so that by April 5th No. 20 had been reached, when they were withdrawn, and a Béniqué passed once daily—from Nos. 40 to 44. So early as the 7th of April, the stricture had begun to shrink again, but this is no more than one expects after slow dilatation with tied-in catheters, however far it may be carried, it is never permanent. However, the end in view had been gained, all feverishness had ceased, the urine had become yellow and limpid, and micturition was no longer painful or difficult.

When seen recently the patient was quite well. He had been passing a sound every day, and washing out the bladder with a weak solution of boracic acid whenever the urine showed any trace of turbidity.

"In these two cases," says the author "it is clear that the source of the mischief lay in an irritated bladder partly filled with putrid and ammoniacal urine, of which a strictured urethra prevented the evacuation. The kidneys, in spite of the pain referred to them, seem to me to have had nothing to do with it, inasmuch as the mere emptying of the bladder sufficed to dissipate both pain and fever. Now that it is the fashion to refer every ailment to the presence of microbes, there is nothing unreasonable in invoking their agency here. So, is it the pyogenic bacterium of MM. Albaran and Hallé, the *bactérie septique* of M. Clado, or some other as yet unrecognized? I really do not know; but there can be no doubt that my patients have afforded every facility for their introduction and development within the bladder. They were under treatment for years before asepsia was dreamt of, and, therefore, never sterilized the elastic rods and tubes they introduced so often and then so rarely, perhaps seldom even, washed them. And yet it is to be noted that it was only when they neglected to pass them that the mischief became really serious. And did these microbes multiplying in the system produce the fever? I cannot believe it. Rather it may have been from the absorption of some toxic agent of their producing—some pyretogen, like that which Professor Hayem lately referred to before the Academy—a substance endowed with such virulency that the minutest quantity introduced into the blood sets up violent fever. But that is poisoning, not infection. And we may imagine that some such poison was contained in the putrid urine, and, so, when it was drawn off, the toxæmia ceased. But is is difficult to reconcile so simple an explanation with the hypothesis of microbian pullulation: and, after all, is there really any need to call upon the ubiquitous microbe or the special poison to explain the symptoms? A large and moderately sensitive viscus is filled with an intensely irritating fluid, so caustic from ammoniacal alkalinity that the mucous lining is in a state of incipient or actual sloughing, and not only with its internal surface bathed in this acrid fluid, but pressed into closer contact by the violent expulsive efforts its evacuation demands. We know what takes place when there is extravasation of urine; the intense inflammation, the sloughing, the gangrenous destruction of tissue, the horrible putridity of the sphacelating area; the hectic, the rapid pulse, the dry tongue and high temperature accompanying it—that, surely, is not due to microbian swarms, nor need we seek any ptomaine more virulent than the decomposed urine has itself developed into. Therefore, may we not say that these cases of special fever were simply the reflex of an inflamed bladder?"

Suppuration due solely to Chemical Agents (*Giornale Internazionale della Scienze Mediche*).—As a commentary on the foregoing article, and in support of the conclusions drawn from it, the observations of Torras y Pascual, may be read with interest. "For some years past the general opinion amongst pathologists has been that suppuration was always the result of microbian action, although some have ventured to sustain the belief that it may, also, be produced by inorganic, or at least by purely-chemical agents. In the year 1882 Orthmann confirmed this by experiments carried out with the most rigorous asepsia, and Councilman, working in a different way, but with the same care, obtained similar results. But since 1885 numerous experimentors, such as Strauss, Klemperer, and Scheuerlen, have stated that except in the presence of microbes it is impossible for suppuration to occur, and this in spite of the researches of Passet and Brewing having fully confirmed Orthmann's theory.

More recently, Rosenbach and Kreibohm have entered npon a new series of experiments, which not only support the latter's opinion, but have found fresh confirmation in the contemporary work of Grawitz and De Bary, who have demonstrated 'that chemical substances absolutely devoid of bacterial organisms—if only used in sufficient quantity and in animals susceptible to their action—will constantly lead to the production of pus.' They explain, also, why Strauss and Klemperer failed to obtain the same results, and that is because they used rabbits for their experiments. In these animals suppuration is induced with difficulty, and especially so with chemical agents; in fact, Grawitz and De Bary obtained exactly the same negative results with them as their opponents had done. Oil of turpentine, for instance, which readily causes the appearance of pus in the tissues of dogs, has no pyogenic action at all upon the familiar rodent.

Rosenbach generally used metallic mercury as the agent. This lodged beneath the skin of rabbits, to the extent of four to eight grammes; leads to the formation around it of a hard, yellow wall, which, when cut into, shows no trace of pus. But the same procedure in dogs leads to the formation, by the third day, of an acute abscess containing abundance of it, but no microbes, their absence being not only verified directly, but by the negative results of cultivation experiments. The method of insertion employed was that of Cohnheim—Councilman. Small glass bulbs containing the mercury are introduced by incision with, of course, all aseptic precautions beneath the skin of the animal, and left there until the wound has healed; then, after a rest of three or four weeks, they are broken subcutaneously by a blow, and the effects watched. The tubes and the mercury were sterilized at the moment of filling, at a temperature of 200° C. It might be objected, however, that even this did not entirely exclude the possibility of germ intervention; but this last difficulty has been got rid of by using antiseptic agents themselves as the irritant. Mikuliez, for instance, has set up active suppuration beneath the human skin by the injection of a strong solution (10 or 20 per 100) of nitrate of mercury. And, in the presence of microbes only, is it not their ptomaines, and not themselves, which induce the formation of pus?"

III.—NOTES FROM FRENCH JOURNALS.

By H. R. HATHERLY, M.R.C.S.

Addison's Disease (*L'Union Médicale*).—Drs. Babés and Kalindero, of Bucharest, have been prosecuting researches into the pathological anatomy of Addison's disease, more especially with regard to lesions of the spinal cord. The result of their labours has been to find in one instance chronic sclerosis of the cord, chiefly affecting the region surrounding the posterior root of the spinal nerves, and leading to neuritis. The demonstration of these lesions is of great interest, as it is possible that the trophic nervous symptoms in Addison's disease are due to them. This case will encourage further investigations in order to establish or throw doubt upon the opinion of Drs. Babés and Kalindero.

Treatment of Hydrocele (*L'Union Médicale*).—Dr. Richet recommends, after puncturing the tunico-vaginalis and evacuating its contents, the injection of the cavity with a solution of bi-chloride of mercury, one part to a thousand of distilled water. About 200 or 250 grammes should be injected, and the walls should be manipulated in order that the fluid may come into contact with the whole of the lining membrane. About 100 grammes of the solution should be left in the cavity. The effect of this corrosive sublimate is to set up an adhesive inflammation, and a few hours after the operation the scrotum becomes tense, red, and shining, as it might appear in erysipelas. It forms a hard, elastic tumour, and the local temperature is increased. After a time the tumour, which is due to effusion, gradually diminishes and disappears. The treatment does not affect the general health or produce salivation.

Medical Women at St. Petersburg (*L'Union Médicale*).—At a recent medical congress of Russian practitioners, 162 qualified ladies were present. Of these, thirty-three were attached to hospitals, twenty-three were in the service of the "zemslvo" of different provinces, eight were attached to municipalities, and two held appointments in manufacturing infirmaries. Of the 162 medical women, 105 practise at St. Petersburg, and the remainder in the provinces.

Fees to Medical Men (*L'Union Médicale*).—The Fifth Chamber of the Civil Tribunal of the Seine has recently decided, that a medical man having once fixed his fee may not raise it, should he afterwards discover that his patient was in a position to pay fees on a higher scale.

Cremation at Paris (*Les Progrès Medical*).—The first cremation, authorised in Paris, took place at the Cemetery of Père Lachaise on the 31st of January last, under the following circumstances :—Dr. Jacoby, a resident in Paris, and who is a member of the Tartar-Backir sect, had the misfortune to lose a son, and he desired, according to the rites of his religion, that the body should be burnt. Thanks to Dr. Jacoby being a foreigner, the authority he applied for was granted. At twenty minutes past twelve the body of the child, wrapped in a cloth of asbestos, was placed in the furnace. The temperature was gradually raised to 800 degrees, and at the end of an hour incineration was complete, leaving a residue of ashes, weighing about two kilogrammes. This is a first step for which the administration must be thanked. It is thought that in a short time cremation may be regularly practised in Paris, for the project has been under the consideration of a ministerial commission to elaborate rules; whilst the matter is actually being discussed by the Council of State.

Resection of the Small Intestine (*L'Union Médicale*).—A case has been reported by M. Anger, in which resection of the intestine was performed for a gangrenous strangulated femoral hernia. The patient was a woman, æt. fifty-eight, and was suffering from strangulated hernia of four days' duration. The operation disclosed that the sac and bowel were gangrenous, ten or twelve centimétres of intestine were removed, and the divided ends were sutured before reduction, which permitted some fœcal liquid to escape. After three days some intestinal matter and flatus escaped, but, nevertheless, and in spite of the formation of two abscesses, the patient recovered. M. Anger has several times observed the escape of blackish fluid from the peritoneal cavity after operation ; he attributes its presence to the effects of taxis, which is often injurious if an operation is necessary. Operation should always be resorted to after the failure of very gentle manipulation.

Creoline (*Bulletin Medical du Nord*).—M. Delbreil, resident at the Asylum of Bailleul, has been experimenting with creoline as an antiseptic. In a case of very obstinate ozæna he obtained excellent results; also in two cases of catarrhal angina. He uses it in a solution, seven drops being added to a litre of water. In the cases above referred to, the remedy was applied on several occasions before the disease was cured. In certain cases of ulcerating tumours, cancer of the neck of the womb, adenoma of the breast, a two per cent. solution of creoline removed all fœtor. In anthrax the good effects were less marked.

A New Method of Producing Local Anæsthesia (*Annales d'Orthopedic*).—In operations of short duration, M. Virturiez advises the use, as a local anæsthetic, of solutions of carbonic acid gas under pressure, of which Brown Séquard was the first to note the anæsthetic properties. Insensibility to pain is obtained by the projection, at a distance of ten centimétres, of the contents of two or three syphons of Seltzer water on the portion of the skin which is to be cut, and the analgesia lasts from four to five minutes. It gradually diminishes so that fresh irrigations may become necessary when a fresh operative period is commenced. It is generally when stitches are about to be applied that a renewal of the anæsthetic is required.

Salts of Copper in Tuberculous Disease of the Wrist-Joint (*Archives de Med. et de Chir. Pratiq.*)—Not long since it was generally held that poisoning by the salts of copper only followed its prolonged employment in small doses. This opinion is losing ground in the present day. Dr. Dumoulin, of Gand, has treated cases of croup successfully with copper in children from three to nine years of age in doses of as much as forty centigrammes daily ; and Dr. Luton, of Rheims, has cured tuberculous symptoms by salts of copper. Dr. Stocquart, of Brussels, has published the case of a young girl, æt. twenty-two, affected with tuberculous disease of the wrist-joint. The treatment consisted in the inunction of an ointment, formed by mixing four parts of sulphate of copper with thirty parts of vaseline. The skin was strongly irritated, but the swelling was reduced, and the joint became more visible. Afterwards the external use of copper was discontinued, but it was administered internally in the form of pills compounded of two centigrammes of neutral acetate of copper, and three centigrammes of extract of gentian. After a few days the patient was able to use the wrist-joint tolerably well. After six months some phthisical symptoms were observed in the right lung, and the wrist again became painful. The same treatment was resorted to internally and externally, and the patient was completely restored to health.

A New and Simple Mouth Speculum (*Revue Illustrée de Polytechnique Médicale*).—Dr. Maximilien Sternberg, of Vienna, has suggested a very simple contrivance for examining the mouth. The antertior portion of the buccal cavity, that is to say, the parts limited on one side by the mucous membrane of the lips and the cheeks, and on the other by the gums, is the seat of a variety of important diseases. Thrush, various syphilitic conditions, mucous psoriasis, ulcerative processes, new growths that need examination and treatment. The ordinary method of examination, which consists in pressing back the lips or the cheeks with a tongue depressor, or the handle of a spoon, is inconvenient, and serves rather to hide than to exhibit the parts which need examination. As for withdrawing the soft parts with the bent finger, or with some special instrument for stretching the corners of the mouth, the method is as clumsy as it is insufficient. He has, therefore, constructed a very simple mouth speculum with wire, which permits the anterior buccal cavity to be examined thoroughly and easily. It is on the principle of Brown's vaginal speculum, which is also made of wire, and is warmly recommended by Chrobak.

Fig. 1 shows the shape of the little instrument, about of a third of its actual size. It is made of a white metal wire, of three millimétres diameter, hard and not elastic. The bent position is introduced with the curve parallel to the row of teeth in the side of the mouth, in such a way as to stretch the cheeks.

Fig. 1.

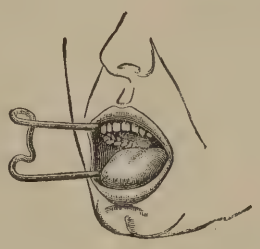


Fig. 2.

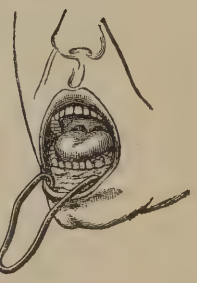

Fig. 3.

Fig. 2 explains the manner of applying the instrument. The other end bent in the form of a hook serves to explore the anterior position of the vestibule of the mouth. The mouth being shut or slightly opened, the lip is hooked down, and everted by raising or depressing the other extremity of the instrument, according to the lip examined. This extremity is bent in such a manner that it is adapted for all variations in the size of the mouth ; the free extremity has only to be held more vertically or more horizontally to obtain either a narrower or a broader speculum. Moreover, the hooked extremity will replace the ordinary instrument for separating the corners of the mouth. With this speculum every part of the external buccal cavity can be readily examined, or submitted to any kind of treatment ; it allows any diseased parts to be dressed, and every little ulceration can he exposed to view ; caustic can be applied, or the parts may be dusted with iodoform, etc. It might also prove very serviceable to dentists. It can also be used as a tongue depressor, if the patient is quiet and does not raise the tip of the tongue. Dr. Sternberg could have remedied this defect by adding a transverse piece, but decided not to do so on technical grounds, and also because the instrument could not be so easily cleansed. As the two ends of the wire are soldered with a substance which does not easily melt, the instrument can be disinfected by baking, or by passing it through the flame of a spirit lamp. A smaller instrument has been made for children.

Homeriana in Phthisis (*Journal de Medicine de Paris*).—The polygomma homeri, belonging to the order of Polygonaceœ, grows in Russia, and contains a green essential oil, which appears to be the active principle. Dr. Laskoff has tried the effect of an infusion of this plant in a variety of diseases of the respiratory tract, and especially in bronchitis and tuberculosis. Out of 112 consumptives in the first stage, ninety were cured. The symptoms which were most noticeably relieved were the hectic fever and the expectoration. At the same time

auscultation and percussion proved a sensible improvement in the pulmonary lesions. It seems that the plant acts directly on the bacillus, either by destroying its own vitality, or in rendering the pulmonary tissues unsuitable for its development. In later stages of the disease the results are naturally less conclusive, but if no cure can be obtained, the most distressing symptoms are much relieved, such as paroxysms of cough, expectoration, and profuse sweating. The plant is administered as a decoction, thirty grammes to a litre of water, which is to be taken during the twenty-four hours.

Soluble Phosphate of Iron *(Journal de Medicine de Paris)*.—M. Jolly has contributed an interesting and elaborate article, showing that the result of his experimental researches is, that iron only exists in the blood under the form of phosphate. The following are his conclusions: The success of treatment by iron, other than phosphated, is subordinate to the richness of the organism in circulating alkaline phosphates; but as no indications can instruct the physician as to the amount of phosphatic alkali in his patient, he can only count upon the benefit of ordinary ferruginous medication. In such case is it not reasonable to prefer a phosphated preparation of iron. M. Ch. Lecerf takes the same view as M. Jolly; and three years ago, at the request of Dr. Viry, he undertook the discovery of a soluble preparation of iron, of constant composition, and capable of being easily assimilated. It is known that the phosphates of iron are insoluble; they are only absorbed through the intervention of the acids of the stomach, which are thus diverted from their special functions to promote the transformation and digestion of food. These conditions of decomposition are not peculiar to the phosphates; they exist for all insoluble preparations of iron, and their prolonged use nearly always induces digestive difficulties. The salts of iron which least affect digestion are those which are soluble in acids of organic origin; but these preparations are only rendered soluble by the decomposition of oxide or of pyrophosphate of iron in the tartrates or citrates of ammonia or potash. These oxides or phosphates of iron are dissolved in a moist state immediately they are precipitated; the solutions thus obtained are dried on glass plates, and supply the flakes which are usually found in commerce. This brief glance at the mode of preparing these iron compounds, show how difficult it is, if not impossible, to obtain products of a stable composition. It became, therefore, desirable to find a ferruginous preparation which should possess always identical properties. In Dr. Lecerf's researches, he only studied the phosphates, being convinced of their value in anæmia, and of their superiority over all other salts, provided that it was not necessary to borrow materials for their solution from the organism. He found that there exists a combination of iron with citric acid, which is very soluble in water, the solution having a neutral reaction on litmus paper. This ferruginous citro-phosphate crystallises in very small crystals belonging to the fourth system, and assumes a rhomboid or hexagonal form. They are slightly raised tablets or lozenges, or in which the angles terminating the longer axis are more or less truncated. This salt, the composition of which does not vary, owing to its crystalline form, offers as a phosphate a peculiarity which may be usefully noted, for it is a rare exception. Generally the ammoniacal citrate is used as a solvent for salts of iron, and all soluble phosphates may be dissolved in this agent. The salt I have described, although soluble in water, is very slightly so in the citrate of ammonia, and if solution is effected by heat, is precipitated when cold. Dr. Lecerf believes that this new salt will prove serviceable in cases where iron is indicated. He adds that this salt, which he has taken himself, and prescribed for many others, does not produce constipation.

IV.—NOTES FROM RUSSIAN, POLISH, AND SWISS JOURNALS.

By Valerius Idelson, M.D., Berne.

Sulpho-ichthyolic Sodium in Gastro-Intestinal Catarrhs.—In the *Vratch*, Nos. 9 and 11, 1889, p. 222, Dr. Alexandr P. Favitzky, of St. Petersburg, writes that certain emphatic statements by Drs. Unna, Nussbaum, Lorenz, and Blittersdorf, have induced him to try the internal use of sulpho-ichthyolate of sodium in twenty-three cases of gastro-intestinal affections in Professor D. I. Koshlakoff's clinic. Of the twenty-three cases, two referred to acute gastric catarrh, four to chronic ones, two to acute enteritis, and fifteen to chronic intestinal catarrh. The drug was given in the daily dose amounting to from six to fourteen grains. The duration of the treatment in individual cases varied between one and five weeks, being mostly equal to two or three. Dr. Favitzky's main conclusions may be briefly given as follows:—1. The best results are obtained from the ichthyolic treatment in acute gastric catarrh; less satisfactory ones in chronic intestinal catarrh; still less effective the drug proves to be in chronic gastritis; and by far less in acute enteritis. 2. Both of the cases of acute gastritis yielded to the treatment in a couple of days. 3. In chronic intestinal catarrh the drug diminished only meteorism and sensation of weight, and pain about the abdomen, while diarrhœa, alternating with constipation, and other symptoms, remained almost unrelieved. In one case diarrhœa even increased, and vomiting supervened. 3. Of four cases of chronic gastric catarrh, in three motions became more regular, but all other symptoms showed no improvement, while one case distinctly grew worse. 4. Of two cases of acute enteritis, in one a slight amelioration at first set in, but subsequently diarrhœa increased and vomiting added itself, the symptoms rapidly disappearing under the influence of bismuth with opium. In the other case, diarrhœa somewhat lessened, but abdominal pain persisted for a long while. 5. Of accessory effects produced by ichthyol, there were observed only vomiting (in two cases) and sometimes short-lasting eructations, appearing soon after the ingestion of the drug. 6. On the whole, ichthyol is by far inferior to many ordinary means employed in treatment of the affections in question. Clinical evidence does not justify us in regarding ichthyol as "a powerful anti-catarrhal means."

On the Biological Action of Fluoride of Sodium.—In the Polish weekly *Gazeta Lekarska*, No. 12, 1889, p. 240, Dr. O. Hewelke, of Warsaw, publishes a preliminary communication on his experimental researches carried out in Professor L. I. Tümas's laboratory, in order to study the biological action of fluoride of sodium (Na Fl). The experiments are divided into three groups, one of which refers to anti-fermentative properties of the salt, another to parasiticide ones, and the third to its physiological action on the animal system. The outcome, briefly given, is this:

a. The anti-fermentative action.—1. A 1 to from 100 to 350 solution of the fluoride inhibits altogether the development and growth of the yeast fungus. The fermentation is markedly retarded or arrested even by a 1 to from 600 to 2,000 solution. An inhibitory influence of the salt may be still noticed, even when dilution oscillates between 1:3,000 and 1:8,000. The effects become *nil* only when the proportion sinks down to 1:16,000. 2. The fluoride manifests a similarly powerful inhibitory action in regard to alkaline fermentation of the urine. While under normal conditions the urine passes into decomposition already in four or five days, a urine mixed with the salt in the proportion of 1:1,300 preserves its acid reaction for fourteen or fifteen days (though the fluid becomes turbid about the seventh day). When the proportion amounts to 1:650 or 1:100, the urine remains unchanged for twenty-one and thirty days respectively. The proportion of urea (which in a normal urine sinks down to a half of the initial one in a fortnight) in a fluoride (1:150) urine is found to be unaltered, even after the lapse of three weeks. 3. The salt possesses a similarly energetic inhibitory action in regard to putrefaction. When mixed with the fluoride in the proportion of 1:80 or 1:170, the blood remains sweet for weeks, its decomposition being distinctly delayed, even when dilution amounts to 1:640.

b. The parasiticide action was studied on pure cultures of certain non-pathogenic (*bacillus fluorescens*, *bacillus prodigiosus*) and pathogenic microbes (typhoid bacillus, bacillus of anthrax, Finkler-Prior's rod, *bacillus fœtidus*, *pneumococcus*, *streptococcus pyogenes*, and *staphylococcus pyogenes aureus*). The drug was added in varying amounts to such nutrient media as broth, peptone gelatine, and peptone gelatine agar. 4. When present in the proportion of 1:150 or 1:200, the salt totally prevents any growth of every one and all of the mycotic species. The effects are still pronounced, even in the presence of 1 of Na Fl in 300 of the medium, and may be still discernible even when the proportion does not surpass 1:300. 5. In general, the fluoride seems to act on pathogenic microbes more powerfully than on non-pathogenic ones. Thus, the growth of the *staphylococcus pyogenes aureus* and bacillus of anthrax is prevented altogether, even when the medium contains only 1 of the salt to 300.

c. The physiological action on the animal system was studied in dogs and rabbits. The fluoride, in the shape of a 2 or 2.5 per cent. aqueous solution, was either injected under the skin or into veins, or introduced into the stomach by means of a gastric tube. 6. When administered hypodermically in small doses (0.02 or 0.03 gramme), the drug does not give rise to any general phenomena, beyond an occasional slight and short-lasting tremor of the whole body. The injection, however, always causes an intense local pain, and (in spite of all antiseptic precautions) is followed on the next day by strong local congestion and œdematous swelling; while about the third or fourth day a rather large, though superficial, slough falls off, to leave an ulcerating surface. 7. When introduced into the stomach, moderate doses (0.04 to 0.05 per each kilogramme of the dog's weight) give rise to salivation, vomiting, general excitement, and tremor, followed by prostration, the symptoms passing away in the course of two or three hours. Larger doses, varying from 0.09 to 0.1 per each kilogramme of the animal's weight,

cause (beside salivation and vomiting) diarrhœa, accompanied by violent tenesmus and intestinal hæmorrhage. The respiration and pulse are at first accelerated, but subsequently retarded, to gradually stop altogether. Of nervous symptoms, there are observed general tremor, followed by extreme prostration, decrease of reflexes, and in one or one hour and a half palsy of the hind limbs. In a couple of hours the animals dies from exhaustion. 8. At the necropsy there are found numberless ecchymoses and extravasations in the stomach (especially about the pyloric region), duodenum, jejunum, and rectum, and extreme contraction of the whole heart. 9. Intravenous injections (in similar doses) are followed by the same train of symptoms.

Professor Peter Mueller on Ovarian Cancer.—At a recent meeting of the Medizinisch-Chirurgische Gesellschaft des Cantons Berns, Professor Peter Mueller, of Berne, has read (*Correspondenz Blatt fuer Schweizer Aerzte*, No. 5, 1889, p. 147) an important paper on the pathology and treatment of ovarian malignant disease. The illustrious author draws attention to the fact that the disease occurs far more commonly than was thought. During the last decennium or so, as many as twenty-five cases of the kind have come under his observation in his clinic. Medullary cancer is met with more frequently than a cylinder-celled variety. In two-thirds of the cases malignant disease is combined with cysts. A one-sided carcinoma is observed as commonly as a both-sided one. The tumours vary exceedingly in their size. As to their shape, sometimes they preserve the outlines of an ovary, sometimes they are globular, while now and then their boundaries are diffuse and indefinite. Their surface is mostly knobby; this feature, however, cannot possibly be regarded as characteristic of carcinoma, since there occur, sometimes, fairly smooth malignant tumours. As regards their consistence, they are either equally dense, or firm areas alternate with softer ones. At all events, "dense consistence associated with knobby surface points strongly to ovarian cancer."

The *etiology* is yet very vague. Of twenty-two patients of Dr. Mueller, eighteen were married and only four single. The proportion is identical with that as found in uterine cancer. All the women came under observation either in the course of climacteric change of life or on the eve of it, or during a *post*-climacteric period.

Symptomatology.—The development of ovarian cancer is often latent, but in some cases the disease develops rather suddenly. In all cases, however, the growth becomes ultimately rapid. The facts may be easily explained by the circumstance that the tumours in question often arise as benign cystoid new growths, and only later on assume a malignant character. Their course is not unfrequently associated with attacks of localised peritonitis. Menstrual disturbances (amenorrhœa, menorrhagia, irregular floodings) are met with in earlier stages almost invariably. Defæcation and micturition are interfered with very frequently. On palpation, the tumours prove to be, as a rule, tender. They are often found immovable, which depends upon the development of dense adhesions and early ascites. Œdema of the external genitals and lower extremities as well as general dropsy with ascites represent a not uncommon occurrence. Ovarian carcinoma is characterized, further, by frequent early metastases.

The *duration* of the disease varies between a few months and two (or even more) years.

The *diagnosis* is based upon such particulars as the presence of climacteric changes, both-sided character of the disease, firm knobby surface, early development of ascites and adhesions, rapid growth, emaciation, serious menstrual changes, and metastases.

The *prognosis* is exceedingly unfavourable, since in later stages an operative *treatment* either proves impracticable, or, when attempted, the operation cannot be completed; or, when completed, is followed by recidives at an early date. As a matter of fact, out of twenty-two cases of the author an operative treatment could only be resorted to in eight, and only five of the eight ovariotomies could be completed. Of the five patients, two died shortly after the operation, while only one of the other three remained free from recidives. Hence, only an early operation may, possibly, promise some success. In view of the important fact that ovarian cancer frequently arises as an apparently benign new growth, the only rational therapeutic plan is to remove every ovarian tumour met with as early as possible.

On a case of Hypospadias simulating Hermaphroditism.—Dr. Alexander I. Voitzekhovsky, of Elisavetgrad, describes a singular instance of hypospadias of a high grade (*Proceedings of the Elisavetgrad Medical Society*, 1888, No. 5, p. 89), found in a recruit, a peasant of twenty, named Poderïak. An inquiry instituted by the author elucidated the following curious particulars: At his birth the patient had been recognised by his parents, jointly with a rustic parson, as a girl, and, accordingly, christened as such. However, on closer examinations performed repeatedly by local peasant women, the latter, anyhow, arrived at the conclusion that the child was a boy. Hence a special female deputation was appointed, which brought the infant again to the priest, and ultimately persuaded him to re-baptise it under a more appropriate male name, Onüfry. After all, their client proved to be actually a boy, since in course of time, during childhood, he commenced to show a distinct aversion to the society of girls, and kept company only with boys; while on reaching his seventeenth year the state of his feelings was quite reversed, that is, he commenced to feel a pronounced inclination towards the better sex, and to have frequent voluptuous dreams, with pollutions; coition, however, proved impossible.

At the examination by the author, Poderïak was found to be a healthy looking, athletically-built, peasant lad, with a yet scanty hair growth on the upper lip, rough voice, male breast, and normally-developed organs of the respiration, circulation, senses, etc.; in fact, with everything reproachlessly normal except his genitals. When examined in an erect position, the patient seemed to have neither penis nor scrotum; the circumstance was partly dependant upon an unusually prominent stand of his pubes (thickly covered with dark curly hairs), which, in its turn, resulted from the patient's habitual method of micturition. When he tried to pass water in the usual male way, his urine would stream downwards in a straight jet, exactly like in women, and, consequently, would wet his drawers and all. Hence, to prevent the unpleasant accident, and to obtain a more or less arched jet, he was compelled to throw his body far backwards and his pelvis forwards, and to bring his abdominal press into strong contractions. At the examination of the patient in recumbent posture, his scrotum was found to be split along the median line into two small-sized fleshy empty sacs, most closely resembling female major labia. The folds, measuring about five centimetres in length, were covered on their outer aspect with scanty hairs; while their inner surface was lined with a pink mucous membrane. Midway between the folds there was seen a transversely elongated opening, one centimetre in diameter, leading into a shallow *cul-de-sac*, similarly lined out with a rose mucous membrane. Between the lower edge of the pubes and the upper one of the intrascrotal hole there was situated a rudimentary penis, about as thick as a finger, and measuring in length along its upper surface five centimetres, and along the inferior only one centimetre. Though furnished with normally-shaped glans and prepuce, the member might be at first glance mistaken for a clitoris, since there was not seen any trace of a urethral orifice. The latter was situated (in four centimetres from the base of the penis, and in eight from the anus) on the lower wall of the *cul-de-sac*. It easily admitted a good-sized metallic catheter, which penetrated into the bladder at the depth of six centimetres. On both sides of the orifice, under the lateral walls of the sac, there were felt two cords running obliquely from the base of the penis towards the anus. The structures were undoubtedly nothing else than rudimentary cavernous bodies of the penis. The inguinal canals contained each a rudimentary testicle, having the size of a small hazel-nut, and situated in six centimetres upwards from the inguinal ring. Both of the testicles could be made (by pressure) to descend into the corresponding scrotal sacs. During pollutions the sperma was seen to flow out of the urethral orifice. When passing into the state of erection, the penis assumed the stage of a hook or arch, the glans pointing downwards. That circumstance, in association with the shortness of the member, made any sexual intercourse impossible.

At first Poderïak's case had been diagnosed by some practitioners as an instance of pseudo-hermaphroditism. But Dr. Voitzekhovsky's careful examination, as sketched above, established the fact that they had to deal with a rare case of extreme hypospadias simulating the former evolutionary defect. In practical regards, however,—in regard to the question whether the patient was fit for military service or not—the said distinction was unimportant, since in either case the man was to be discarded from the list of recruits.

Iodoform in Burns and Scalds.—In the Moscow therapeutic weekly, *Novosti Terapii*, No. 10, 1889, p. 147, Dr. Afanasy S. Shtcherbakoff, of Rostov-on-Don, warmly recommends the local use of iodoform as an excellent and innocuous means for burns and scalds of any degrees and kinds, both in adults and children. He employs an ointment made of one drachm of iodoform to one ounce of white vaseline. Having freely spread the salve over a sufficiently large piece of iodoform gauze, he applies it to the part injured, covers the gauze with a layer of hygroscopic cotton wool, and fixes the dressing with a roller bandage. Having resorted to the treatment in a large number of cases, the author never yet observed any unpleasant accessory symptoms pointed out by Koenig, Winiwarter, etc. Hence, he emphatically suggests to give an extensive trial to the method which, in addition to its being effective and safe, is very simple and convenient.

On the Treatment of Diphtheria.—In the *Novosti Terapii*, No. 10, 1889, p. 145, Dr. Afanasy S. Shtcherbakoff says that he obtains very good results from the following treatment of diphtheria: 1. The throat is brushed, several times daily, with a glycerine (two drachms) solution of boracic acid (fifteen grains) and *oleum martis* (one drachm). 2. Steam inhalations of lime water are made every ten minutes. 3. In addition, the following gargle is administered:

℞. Iufusi herbæ salviæ..... ..... llj.
Biboratis sodæ ..... ℥j.
Mellis despumati ..... ℥ss.
M. To use frequently.

4. Internally, antipyrin, in full doses, twice daily, is given. 5. A liberal diet with wine is ordered. To secure successful results, however, the treatment should be resorted to as early as possible.

V.—OBSTETRICS AND GYNÆCOLOGY.

AT a recen tmeeting of the Philadelphia County Medical Society Dr. JOSEPH PRICE read the following paper on **Gonorrhœal Diseases of the Uterine Appendages.** The attitude of numbers of professional men who express eitherin credulity or absolute disbelief in the causative relation between gonorrhœal disease in women and pyosalpinx and abscess of the ovary, is sufficient justification for a still further discussion of this subject. My views upon the matter are based neither upon theory nor upon microscopic examination. They are from surgical experience only, or from confessions of men whose wives have been diseased by them. From the time that Noeggerath first formulised his belief upon this subject it has been smiled at, contradicted, or controverted, but never in its essentials disproven. In his earlier paper, Noeggerath fell into the common error of enthusiasts, that of attributing too much to his discovery, and claiming too wide a pathological field as the sequelæ of this trouble. This, without doubt, led many otherwise fair-minded men to pass over his paper as unworthy of attention, thus impeding the progress that otherwise would have followed its discussion and the observations based upon its claims. In taking up most later surgical works we find the etiology of ovarian and tubal disease considered from this standpoint omitted—a missing link, or differentiated out of sight. This is wrong. As early as 1877, Mr. Lawson Tait and others insisted upon the relation existing between gonorrhœa in man and tubal disease in women. Noeggerath antedated him about five years. Mr. Tait also insisted on its causative relation to perimetritis, this as late as 1883. Schœder, in the early editions of his "Gynœcology," insisted upon this as bearing a causative relation to ovarian and tubal troubles. In the very latest edition he says:—"Gonorrhœa, in the highest degree, appears as a causative disease in women." Sänger also is an ardent advocate of the same belief. He is wrong, however, I am persuaded, in holding that the gonorrhœal infection is alway late in revealing its presence in the woman when transmitted by the man. To this subject I shall refer later. Without further collation of authorities upon this subject, I shall proceed briefly to its discussion. Whether or not the presence of the disease can be diagnosticated absolutely by the presence of the gonococcus of Neisser, is of small importance, if by the chain of common evidence we can connect the presence of one disease with the other in their sequence. If, on discovering tubal disease in a woman who has never aborted nor had any of the diseases incident to childbed, who has been healthy up to a time, after which vaginitis has occurred, contracted from her husband, after which the woman from time to time experiences increasing pelvic pain, losing strength and weight, the case, it seems to me, is made out, save as quibbling may dispute it. This history occurs in most of the cases I have handled. Of the many cases that have come under my observation, I choose the following as illustrative and typical:—A young married woman, one child. Her recovery from childbed excellent; no gonorrhœal infection of the child at birth. Some months afterwards she had inflammation of the vulvo-vaginal glands, with suppuration. Later she appeared with abdomen tense and painful, enlarged tubes and ovaries, tender and painful on the slightest movement or pressure; she had lost in weight and strength. Her husband confessed to the infection of his wife. The diagnosis was made of gonorrhœal pyosalpinx, and operation proved the correctness of the opinion. Both tubes contained pus, were cheesy and friable, the ligatures cutting through all but the vessels. The abdomen was full of fluid, and the intestines gave evidence of acute peritonitis. The history here is complete, leaving no possible doubt as to the origin of the disease. The early infection here exhibited is at variance with the views of Sänger, and shows that his statements are not necessarily correct, or accidentally correct, if at all so. There is no sufficient reason why this infection should not be early. I incline to the belief that the disease originates early, but may be slow in its progress, and thus escape attention and discovery.

The discussion on **Gonorrhœal Disease in Women** was opened by Dr. J. WM. WHITE. He said: I had not intended to take part in the discussion, but as you have kindly asked me, Mr. President, I will say that neither the paper read this evening, nor anything else that I have heard or read, has convinced me of the frequent relation between tubal disease in the female and gonorrhœa in the male. I believe that such cases as Dr. Price details are defective in some important point. They assert that the occurrence of suppurative disease of the tubes is a consequence of preëxisting disease in the husband, or of the individual with whom the woman has had connection. It seems to me that by a similar process we could demonstrate the relation between gonorrhœa in the male and mitral disease, cataract, or other ailment in the woman. This is another instance of the *post hoc ergo propter hoc* line of argument. It is carrying a theory, which has an undoubted basis in fact, to great extremes, and, as regards the views of Noeggerath, to ridiculous extremes. His sweeping assertions in regard to the persistence of latent gonorrhœa in the male, and his theory that women having connection with men who had ever had gonorrhœa, are constantly rendered barren, or if they do conceive do so only to abort, and that such women are the constant subjects of ovarian and tubal disease, are, I believe, contradicted by the practical experience of every surgeon and general practitioner. I have had rather exceptional opportunities for examining cases of gonorrhœa in the male. Many of these cases have married, and the majority of them had, and still have, healthy wives and healthy children. While there is undoubtedly some foundation of truth in regard to this matter, and while there are undoubted instances of this form of infection, and while gonorrhœa in the male may produce vaginitis, cervicitis, endocervicitis, and pyosalpinx, yet it seems to me that these occurrences are exceptional, by no means so frequent as is claimed, and certainly not the rule. Dr. Price does not assert his belief in these views, but I am surprised at the favourable tone of his comments upon them. I have always regarded the theories of Noeggerath as examples of the extremities to which an enthusiast may be led, and only to be fitly characterised by the somewhat strong terms of absurd and ridiculous. Certainly in my personal experience I have never seen anything to warrant a belief in the relation of these two conditions, as cause and effect, in any very large proportion of cases. The pathological side of the subject, to which Dr. Price merely alludes, is, after all, the one of greatest importance. If gonorrhœa in the male is, as Noeggerath describes it, latent in a majority of cases, it must be that it depends on a peculiar microörganism, and the invariable association of the gonococcus, or some other low form of animal life, with gonorrhœa must be demonstrated. In this "latent" gonorrhœa, described by him, there may be no symptoms, and nothing which would enable the practical specialist in venereal diseases to recognise the presence of the affection. There must then be demonstrated at least that some microbe is present which belongs to gonorrhœa and produces the disease whenever it develops in the urethra. In order to demonstrate the relation between latent gonorrhœa and these diseases of the tubes and ovaries, some such microörganism should also be found in these latter cases. I believe that in certain persons the nidus for the multiplication of the organism is exceptionally favourable. In such cases it rapidly multiplies and tends to spread, and increases the severity of the disease. These are the cases, I doubt not, in which tubal disease follows infection. That it is frequent, or that there is demonstrated any invariable relation between the existence of the microörganism and such disease in the female, I do not believe has been proven. The clinical relation of the two conditions being, therefore, to my mind at least, not established; and the pathological evidence being entirely wanting, I am compelled to reject as unproven and unfounded the theories which so closely associate an antecedent gonorrhœa in the male with so many forms of disease of the uterine appendages. I believe these theories to have been harmful in their influence upon gynæcological practice in having given apparent justification to a large number of operations, a fair proportion of which I do not doubt will be shown within the next ten years to have been unnecessary and injudicious.

Mr. HOFFMAN said Dr. White's remarks show how two persons interested in the same subject may arrive at entirely opposite conclusions. Dr. White has had abundant experience in dealing with these cases, especially in the almshouse, in a class of people where he would be supposed to see the relation between gonorrhœa in the male and certain diseases of the female, especially in the uterine appendages. He, however, fails to connect the two in any marked degree. Bernutz has written a very remarkable work, appearing in the New Sydenham publications a few years ago, and the conclusions which he reaches are diametrically opposed to those of Dr. White. Bernutz, in examining ninety-nine cases of pelvic peritonitis in women, concluded that twenty-eight were distinctly attributable to gonorrhœa; forty-three were traced to childbirth, and eight of the childbirths were abortions.

If you take away the forty-three cases, due probably to infection from some incidental cause, we have remaining fifty-six cases, of which twenty-eight, or 50 per cent., were traced not only theoretically, but by a post-mortem examination, to gonorrhœa, all other causes being eliminated. Taking his statistics of the twenty-eight cases which he considered analogous to orchitis in the male, we have twenty menstrual and eight traumatic. The causes of traumatism were, in three, venereal excesses; two, syphilis of the cervix; two, the introduction of the sound; and one, the use of the cold douche during menstruation. I have myself seen this condition so frequently that I cannot regard it as an unusual accident, and all the less after reading the remarkable record of which I have here a note, can I think that it is accidental. So far as Noeggerath's views are concerned, I think that Dr. Price sounded their value. His views are extreme, and we may as well, now as ever, regard them as extreme. There is no use in laying down the principle that only one cause can produce the disease. The original paper of Bernutz, published in 1857, antedating the publication of Noeggerath, is to me convincing. Whether or not we always find the gonococcus of Neisser is to me a question of indifference, and not always decisive. We know very well that one microbe will, by its presence, crowd out another. When we open the abdomen and find the tubes filled with stinking pus, in which putrefactive changes have taken place, I am not surprised that the gonococcus is not found, its place being taken by some other form of micrococcus. In such cases I do not believe that the gonococcus is diagnostic.

Dr. WHITE said the statistics of Bernutz and Goupil, to which reference has just been made, are quite familiar to me, although it was my impression that they were published in 1861, not 1857. This is quite a different question from the one I was discussing. These were prostitutes of the lowest class undoubtedly infected with gonorrhœa. The proportion of these cases in which pelvic peritonitis occurs is considerable. This is entirely distinct from the cases in which you depend upon the history of a previous and often a long distant gonorrhœa in the husband, to explain ovarian and tubal disease in the woman, but in which you have no consecutive history of true gonorrhœal infection of the female. It is to this that I object, not to the assertion that pelvic peritonitis and pyosalpinx *may* occur in some cases of gonorrhœa, particularly in women of the lower classes. Dr. Hoffmann has missed the point of my remarks. I have quoted the statistics of Bernutz in a paper which has been accepted by the *British Medical Journal*, although not yet published. They simply present the records of two of the French hospitals to which the lowest class of French prostitutes are admitted, women broken down in health, and the subjects of virulent forms of gonorrhœa. This is entirely distinct from the proposition of Noeggerath, which connects not only existing disease in the male, but also precedent disease of which all active symptoms may have disappeared, with certain conditions of the female, barrenness, tendency to abortion, and diseases of the uterus and appendages. It is to that I object, and not to the assertion that in a large proportion of cases these complications occur in prostitutes with well-marked gonorrhœal infection.

Dr. M. PRICE said in regard to the statement of Dr. White that these diseases are more peculiarly connected with these hospitals and these women of low character, I would say that all the cases that I have had in private practice, six or eight in number, have been not only of the better class, but among the best women of this town. The specimens from one of these cases I should like to show to the Society. This pair of tubes is unquestionably gonorrhœal. I treated the man some ten years ago. I afterward treated his wife for old-fashioned cellulitis and peritonitis. She has had five attacks during the last eight years, in every one of which there was high temperature and quick pulse, with the pelvis filled with inflammatory masses. These inflammatory conditions were cured about as the electrician cures pelvic abscess and pyosalpinx. The health and vigor of the woman were sufficient to cause absorption of the liquid portion of the pus, and for a time the disease was kept in abeyance. Four or five days ago I removed from this woman's pelvis a pint of pus of the most offensive character. This was her last struggle, her last effort to get rid of it. She was unequal to the task, and was slowly dying of a septic condition. The symptoms were of such an urgent character that I opened the abdomen and removed both tubes. There we have a marked case of pyosalpinx unquestionably of gonorrhœal origin. Out of the eight or nine cases of pelvic trouble I have had occasion to operate on, in all but one I could distinctly trace a gonnorrhœal origin. In every one I had treated the man for gonorrhœa. From that day not one of these women bore a child. They always complained of symptoms of pelvic trouble, pain on pressure, pain on movement, and pain on slipping or jarring. The trouble in these cases was just as certainly gonorrhœal in origin as that any trouble existed.

Dr. J. M BALDY said the views of Noeggerath, Burnutz, Sinclair, and others, including the author of the paper, are very extreme, and grossly misrepresent the facts. Venereal disorders in men are not so frequently the cause of pelvic inflammatory diseases in women as these men would have us believe. I think with Dr. White, that in order to settle this question, we must have more than mere clinical evidence; we must also have pathological research and experimentation. So far as the clinical aspect of these cases is concerned, I may say that the vast majority of them coming under my observation are not women who have never been pregnant. There is almost always a history of abortion or labour, with septic trouble at that time. Sinclair has demonstrated that most of these patients have the gonococcus present in the secretions of the vagina and uterus, and for that reason he has considered the disease to be of specific origin; in some cases where the gonococcus was not found he still believed the disease to be of specific origin, supposing that the gonococcus had been crowded out by other forms of micrococci.

Dr. PRICE said we now care nothing, or next to nothing, about what Noeggerath wrote, for we possess sufficient clinical material in our own surgical experience to prove that gonorrhœa, and nothing but gonorrhœa is responsible, except in rare instances, for the pathological conditions with which we surgically daily deal. Dr. Deaver and Dr. White have proven this in their own daily experience by sections for pus tubes due to gonorrhœa. In the class of patients met at the almshouse, among the males there is no question as to the great prevalence of gonorrhœa. Among the females it exists about as often. In his description of a case, in the *Medical and Surgical Reporter*, December 15th, 1888, Dr. White says: "Two small patches of ulceration existed on the floor of the membranous urethra, each measuring about two lines in diameter. This case may be taken as a type of the many cases of which no microscopical examination can be made, or at least is made. Further on, in this same paper, a troublesome case of gleet is noticed, having existed for several years. That the presence of gleet is a real source of infection is no longer doubted. Why then dispute that an existing cause of trouble must stop short and lose its virulence as soon as it touches the female organs? Among the complications of gonorrhœa in the male, noted and admitted by good authorities, are peritonitis, subperitoneal abscess, perinephritic abscess, together with the only too frequent lesions of the bladder, prostate, and kidneys. Now, if peritonitis can occur with gonorrhœal origin through the roundabout road of the vasæ differentes and seminal vesicles, how much more likely is it to occur in women by the direct route from the vagina, through the uterus and Fallopian tubes to the peritoneal cavity? Sinclair, in his little book, faulty and full of shortcomings as it is, proves without doubt that most of the cases of pelvic peritonitis attributed by him to gonorrhœa are rightly so ascribed. Out of fourteen cases cited, in three the diagnosis is not proven, and may be regarded as doubtful. It is the danger of every enthusiast to see too much in his theory. This was the cause of the slow reception of the theory advanced by Noeggerath. Noeggerath's view is not a new one; it is only the wide application that causes it to differ from opinions held long before. I can readily understand why the profession should be practically ignorant of the ravages of this disease. Nothing short of a rigid special training will enlighten the profession in this field. Again, it is additionally strange that in this age of boasted progress the profession should question the great prevalence of gonorrhœa in the female, knowing it to be so very common in the male. Many important investigations have been made by Bumm, Sänger, and Oppenheimer. Donné, in 1844, discovered a parasite in the urethral discharges, which he named trichomonas vaginalis. It is folly here to allude to the numerous small beasts that have been found in genital discharges—forerunners to Neisser's gonococcus. The latter presented his researches just at a time when the world was prepared to accept anything in the shape of a small beast. Clinically it is not necessary to determine the presence of the gonococcus to establish the infective virulence of gonorrhœal pus, and this I believe is in accord with the many researches on the subject. Considering it from a pathological and surgical point of view, a clear history of recent impure sexual contact, in the presence of certain well-known clinical features, ignoring the presence or absence of gonococcus, will be accepted as sufficient evidence of the vice, and responsible for a large number of grave pelvic diseases, a much larger number than puerperal fever or syphilis are responsible for. I think that I could easily prove my position by using the clinical evidence from my own college mates. I have taken pains to look them up, and investigate their histories, that I might draw some conclusions. I think that I can prove a casual relation in that way, having personal knowledge of their contamination.

Dr. H. A. Kelly exhibited the specimen of a **Carcinoma of the Corpus Uteri.** Mrs. F——, æt. forty-five years, married, applied to him in October, 1888, for the relief of persistent uterine hæmorrhage. She was the mother of two children, twenty-three and nineteen years ago. Her health was always good until 1886, when the present trouble began, as if her menstruation was appearing too frequently. The discharge soon

became constant. The only impression made upon her general condition was a marked anæmic, sallow cast of the skin. Aside from this, she suffered from an agonizing pain in the right ovarian region. The uterus was anteflexed, very large, measuring 3¾ inches in length, choking the pelvis, emitting a sanious, fetid discharge. She was admitted to the Kensington Hospital, and a handful of débris, looking like a sloughing fibroid, removed by scraping. This proved to be cancerous, and in the presence of Drs. D. Emmett, Vanness, and Gramm, assisted by Dr. H. Robb, I removed the uterus by vaginal hysterectomy. On account of the severe pain she had felt since February last, and the impossibility of outlining the structure in the choked pelvis, he feared some infiltration into the broad ligaments, a contra-indication to vaginal hysterectomy. He therefore made a preliminary exploratory abdominal incision, passed his fingers in carefully, explored the pelvis, found it free, got his bearings for the subsequent operation, and closed the incision in ten minutes. The operation was done with great difficulty, owing to the great size of the uterus. The worse bleeding came from the incision in the vaginal walls. The tissues above this were tied off in small bundles with silk ligature. He tried to follow the plan advocated by his friend, Dr. Dudley, of Chicago, of clamping the vessels, but the uterus was too large, and he could not introduce his fingers and fix the clamp at the same time. The right side was freed first, the uterus delivered, and the left side pulled without the vagina, and the left broad ligament tied off, and a uterus freed the size of a three-months' pregnancy. The vagina was packed with iodoform gauze, which was renewed in a few days. The ligatures did not all come away until several weeks had elapsed. Her recovery was interrupted by a variety of curious complications which it would take too much time to describe. It could be noticed that the uterus exhibited the specific differences between cancer of the corpus and of the cervix uteri. When first removed, the inner surface of the uterus was covered with a greenish slime, very stinking. The whole mucosa of the body was a mess of polypoid excrescences of variable size. The uterine ends of the tubes were not affected with the disease, nor was the cervix.

Dr. Kelly also exhibited two large sarcomatous ovaries, removed from a woman forty-three years of age. She had a marked cachectic appearance, suffered with knife pains in the lower abdomen, and had had metrorrhagia for sixteen months. He found two large irregular masses in her abdomen, which were obscured by fluid in the peritoneum. The uterus was jammed against the symphysis. At the operation, after tying off a number of omental adhesions to the right mass, it was found to be a soft, friable tumour, with a sessile attachment involving the whole broad ligament. The tumour broke down and bled profusely upon raising it. The broad ligament was quickly tied off by an interlocking series of interrupted sutures. The lateral wall of the uterus continued to bleed actively, and he had to resort to a device which has saved lives for him on several occasions. The cornu uteri was caught in a pair of bullet forceps, and raised forcibly up into view and carried over to the left side, while he passed a stout ligature in the cervical region deep through the uterus, with a view of tying the uterine artery. This checked the hæmorrhage. The tumour behind the uterus came out in handfuls, leaving a bare left broad ligament, which was treated in the same way as the right, including the ligature to the uterine artery. A drainage tube was left in, and the incision closed. Five hours later he was called to see her, and found a steady venous flow from the tube, which had saturated all the dressings. He put her under chloroform at once, placed the operating table directly under a side gas-light, and cut all the stitches, turned out the intestines, and found an active flow from a spot in the right pelvic wall. She made a good recovery as far as the local trouble was concerned, but a mass at the pylorus leaves room for suspicion that the disease in the pelvis was not the only focus. The tumour proved to be soft, round-celled sarcomata. This is the second case of sarcomatous disease of the ovaries he has operated upon. The first was a young girl of twelve. Both cases recovered.

Dr. Wm. Ashton exhibited a species of **Ovarian Sarcoma.** Mrs. Sarah G——, æt. thirty-five years, was admitted to the Jefferson Hospital on the 27th of last November. Puberty at fifteen years. Always regular, except when pregnant, up to two years ago, when her last child was born. At this time noticed a small tumour in hypogastric region, and to the right side. During the first year the growth was slow, after which it increased rapidly in size. She had lost a great deal of flesh, and was much emaciated. A diagnosis of ovarian sarcoma was made by Professor Parvin. Through Dr. Parvin's kindness he operated on the woman a few days later, assisted by Dr. Baldy. The tumour was found to fill the whole of the abdomen, and was universally adherent. Many of these had to be tied; and when the mass was removed, it was found that the whole posterior portion of the bladder and the uterus, as well as the fundus, had been adherent to it, and these points of adhesion oozed freely. Ligatures and Monsel's solution were used freely, and the bleeding stopped. The whole cavity was then thoroughly irrigated with warm water and the incision closed, with drainage. She died in six hours of shock. An examination of the specimen by Dr. Coplin shows it to be a spindle-celled sarcoma, with points of beginning degeneration, and some points of slight hæmorrhage.

Dr. Wm. S. Stewart exhibited exhibited **a Cyst of an Ovarian Tumour,** weighing eighty-four pounds. The operation was performed upon Mrs. ——, æt. sixty-one years. General health good. No marked emaciation. Abdomen enormously distended. Facia ovarianía very perceptible. He made an incision about two inches in length. Sac was emptied rapidly by a large trocar. Found general adhesions to the anterior abdominal walls; these were separated by a rapid sponging off, which had proved of advantage in preventing hæmorrhage and traumatism. The cyst was delivered as the adhesions were sponged off. Operation lasted forty minutes. No irrigation; no protrusion of bowels or omentum; slight oozing; glass drainage tube; only five stitches needed to close incision. Weight of sac and contents was eighty-four pounds. He was assisted by Drs. Joseph Price, W. H. Kirk, and Dill. Having seen the patient these three succeeding days, found everything progressing favourably. Temperature normal; pulse eighty-four; respirations twenty-two; oozing about ceased; drainage tube removed to-day.

Dr. J. Price read for Dr. R. Stansbury Sutton, of Pittsburgh, the following:—**Operation for Congenital Deformity.** Miss A. P——, æt. twenty. Never menstruated. Has severe pain in lumber region, abdomen, and head every month, but no flow. Vagina short, cervix uteri not felt anywhere; no uterus discoverable by bi-manual palpation through the rectum. Often vomits, is unfit for work, is melancholy. Laparotomy December 10th, 1888. Uterus unilateral, one horn one-half inch long, as thick as the first joint of the little finger. On the left side uterus not developed: no lig. lata., no tube, no ovary. On right side small lig. lata., large tube and full sized ovary, with two distended egg cells on surface. Ovary and tube removed close to cornea of the one-half uterus. The external genitalia were fully developed, the vagina about one-half ordinary depth, and blind at upper end. A note from Dr. Sutton, dated January 1st, says Miss P—— has gone home well, All of her morbid symptoms, mental in character, are gone. He adds that he has had thirty-four consecutive ovarian operations with one death, and twenty-seven sections for all kinds done with one death. All hospital work.

Dr. C. P. Noble read **A New Method of Diagnosis in Obscure Cases of Entero-vesical Fistula.** He had been recently asked by Dr. C. M. Wilson to see a patient supposed to be suffering from fistula. It was not his purpose to report the case in full. Briefly, the woman had what is called an ischio-rectal abscess about five years before. Some time after this abscess discharged she stated that she began to pass wind and small pieces of fecal matter, *per urethram*, at irregular intervals. No symptoms of bladder irritation existed. An extensive cicatrix, following ulceration produced by a pessary, is present in the vagina. It extends along both sides of the vagina and across the posterior fornix (behind the cervix). In view of the absence of bladder irritation and the well-known haziness of the knowledge of anatomy possessed by the laity, it was thought likely that if the fistula did exist it was thought likely that if the fistula did exist it was a recto-vaginal fistula. A careful examination, under anæsthesia, by touch and sight, made by Drs. Wilson, Hawley, myself, and others, failed to demonstrate the existence of any fistula communicating with the vagina. But two conclusions could be drawn: either the woman was right, or else she was a malingerer. The latter seemed probable from what was known of her. It was suggested that a careful and extended study of the urine, made with the microscope, might determine the diagnosis—particles of vegetable fibre or seed of small fruits might be found. This plan involved much labour and time. It occurred to him that the hydrogen gas test would settle the matter quickly and positively, and he suggested that it be employed. The recommendation was accepted and followed the next day. Dr. Wilson forced the gas into the rectum, and lighted the gas at the end of a catheter introduced into the bladder. Dr. Noble was unable to be present at the time, but Dr. Wilson told him that no gurgling sound was heard (caused by the gas passing the ileo-cæcal value), hence it seems plain that the communication exists between the bladder and large intestine. Dr. Noble offered this as a new and valuable method of diagnosis in obscure cases of entero-vesical fistula; or, if you choose, a new application of Senn's hydrogen gas test.

Dr. C. M. Wilson reported a case of **Lack of Development of the Fingers and Toes in a Child Delivered at Term.** The mother of the child applied for admission to the Philadelphia Lying-in Charity, November 29th, 1888. Upon examination she was found to be active in labour, and was immediately admitted to the lying-in ward. The membranes had ruptured, amnoitic fluid had escaped, and dilatation

was nearly completed. The labour terminated naturally and with great rapidity, the second stage lasting but one hour. The woman was a primipara, married, a native of Philadelphia, and a housemaid by occupation, æt. 25 years. She stated that she had experienced no fright or trouble during her pregnancy. She gave a very clear account of the members of her own and of her husband's family, and stated that no deformity had existed on either side for at least two generations. She made a rapid and normal convalescence from her delivery. The child weighed eight pounds, was fully developed with the exception of the deformity noted. The deformity consists in a lack of development of the majority of the phalangeal joints of the fingers of both hands and of both feet; in the absence of the nails upon nearly every finger and toe, and in the web-like folds of skin connecting several of the fingers of either hand together. The appearance of the constricting band on the right great toe would seem to give colour to the idea that possibly the deformity was due to intra-uterine amputation. The fact that some of the finger-tips sloughed off after birth would seem to strengthen this supposition. He believed, however, that the deformity was due to lack of development. No history of syphilis on the part of either parent could be obtained.

Dr. Parvin presented the **Sexual Organs of a Young Girl.** They are among several which he procured in Munich last autumn for the purpose of teaching students practically many of the operations upon such organs by the method proposed and pursued by Prof. Winkel—that is, the organs being properly fastened within and upon Schultze's obstetric phantom, many of the more common operations can be made by the students as upon the living subject. This much was said to explain why he had no history of the subject from which the specimen was taken. It will be observed that there is a very perfect annular hymen, one of the rarer forms of this structure, and its borders are quiet regularly dentated. The bladder apparently has its walls somewhat thickened, though probably not really; but certainly they seem very thick in comparison with the uterine walls. These latter are so thin that there is, in this regard, a hypoplasia of the uterus, and thus a uterus membranaceus, but the organ in length and breath seems fairly developed.

Dr. Parvin also presented an **Obstetrical Manikin.** The obstetrical phantom shown, he had made in Munich, and represents a design he had entertained for many years, in fact, since the beginning of his obstetric teaching. He wished a complete human form that could be put in the different positions a woman occupies in labour, natural, manual, or instrumental. The joints are sufficiently mobile so that the model can be place on the side or on the back, the limbs put in any position desired. The pelvis is of iron, covered with leather, and has a movable coccyx, while the external parts are made of rubber, which will dilate so as to admit the passage of a fœtus. The abdominal cavity is ample for the introduction of two fœtuses. One or both may be included in the rubber uterus designed by Prof. Winkel, and thus placed in that cavity. For the suggestion of a cast-iron pelvis, a model of the best one found in the Museum of the Munich Frauen-Klinik being made by which the cast was formed, I am indebted to Dr. J. Clifton Edgar, of N. Y., then a resident obstetrician in the Klinik. Dr. Edgar, who remained in Munich several weeks after I left, during his stay superintended the work, and doubtless I am indebted to his intelligent supervision, suggestion, and direction for the successful manner in which the workman carried out the original design. The model will be useful in gynœcological as well as in obstetric teaching, in that the different positions in which the patient is placed in examinations and operations can be readily and plainly illustrated. The only addition which it seems to me at present might be usefully made is a rubber abdominal wall similar to that of Budin's well-known obstetric manikin.

Dr. Kelly remarked that the condition of the hymen was a subject of much interest, about which many erroneous views prevailed. It was by no means uniformly ruptured by coitus. In other cases coitus alone was as capable as numerous pregnancies in obliterating all traces of the hymen. He had made many observations and careful drawings of a number of cases which showed a definite relation between a certain condition of the hymen and severity of a preceding labour; that is, where the vaginal outlet has been broken down, with extensive laceration, the hymen remained *intact*, except at the split posteriorly, being saved by the vaginal tear. On the contrary, the surest way of thoroughly destroying the integrity of the hymen was the equable, all-around dilatation of a *normal* labour. In a forceps case examined some months after labour, the hymen, elsewhere intact, was as cleanly cut into halves as a lacerated cervix. It is unquestionably, as Budin has shown, the pointing terminus of the vaginal canal.

Dr. B. C. Hirst showed a specimen of endometritis gravidarum polyposa from the University Museum; there are in the Museum two other examples of the same sort, one recently contributed by Dr. R. Deaver, of Germantown. In the last case the embryo was certainly not over three weeks old; the ovum corresponded to the third month, and had been retained in the utero some six months after the death of the embryo. They are all very good specimens of a very rare disease. He also showed a *pregnant uterus* removed from a woman with chronic nephritis, who died suddenly from apoplexy within three months of term. She had been blind for three weeks before her admission to the hospital, and was œdematous in face and extremities. As soon as his attention was called to the case, he ordered premature labour to be induced, but before this could be done the woman died. The uterus showed, on abdominal palpation, an apparent right lateral version. On opening the abdomen this was seen to be due to the altitude of the fœtus (vertex presentation, L.O.A.). The uterine body extended equally to both sides of the median line, but had not the pyriform shape supposed to be characteristic of the pregnant organ. It was irregularly triangular in form, the base of the figure being to the right side, the apex to the left. This would give one the impression, on abdominal palpation, of R. lateral version, from the fact that the highest point of the uterine fundus was to the R. side; but this point corresponded to that angle of the uterine cavity on which lay the trunk and extremities of the fœtus.

The Spirit of the Societies.

Clinical Society of Manchester, Tuesday, April 16th (Dr. Leslie Jones, president, in the chair).—Dr. W. N. Maccall read a paper upon the **Treatment of the various forms of Rheumatism.** After reviewing the previous treatment of acute rheumatism during the last twenty-five years, Dr. Maccall considered the value of the present routine treatment by salicylic acid and its allies or derivatives under the following headings. 1. In relieving pain and lessening fever in acute rheumatism the salicyl treatment is undoubtedly the most effective we know of. 2. The salicylates do not prevent the rare complication of hyperpyrexia, and are absolutely useless in its treatment. 3. It is doubtful if they prevent endocardial or pericardial troubles, the percentage remaining about the same (50 per cent) since the salicyl treatment as before. They seem to have no influence in curing these troubles when they do occur. 4. There is no proof that the salicylates prevent relapse. 5. It is not proved that the salicylates lessen the duration of the disease, nor that they prevent anæmia. With regard to the particular form of the remedy, most writers recommend (and Dr. Maccall agrees with them) salicylate of soda in twenty-grain doses at first every hour for three or four hours according to circumstances. It should be continued in diminishing doses for at least eight or ten days after all pain and pyrexia have gone, and in most cases should be followed by iron. Salicylic acid, salicin, and salol may be tried in exceptional cases where the soda salt is not well borne.

In young children antipyrin may be substituted with advantage. In convalescence, Sir. A. Garrod's alkaline mixture, followed by iron, was advised; and if any joint remained stiff or swollen, blistering or painting with iodine was useful.

Dr. Addy made some remarks on his experience of the blistering treatment, preferring however the salicylate of soda, and laying special stress on combining with the latter drug alkalies and an opiate to relieve pain.—Dr. Braddon confessed himself as disappointed with the salicylate treatment, and preferred as a rule the alkaline, combined with Dover's powder.—Dr. Hill Griffith asked if Dr. Marshall had ever tried acupuncture of the joints.—Dr. Hirst usually prescribed salicylic acid dissolved in liquor ammonia acetatis, in frequent and small doses. Opiates he found nearly always necessary.—Dr. W. C. Martin referred to insidious pneumonia occurring in acute rheumatism, and also to the treatment of hyperpyrexia.—Dr. Railton considered that salicylic acid or its salts was comparatively useless in acute rheumatism, except as regards the relief of pain. It warded off no complications, and did not prevent relapses.—Drs. Owen, Scott, Simpson, and Tinker also took part in the discussion.

Medical Society of London (C. Theodore Williams, M.D., president). **On Tropical Diarrhœa as seen in this Country.**—Sir Joseph Fayrer read this paper. The subject of these remarks is a peculiar form of diarrhœa which derives its origin from tropical and sub-tropical countries, notably India, China, Ceylon, Java, etc., and which is of pregnant occurrence in Europe wherever old residents of tropical climates reside. Its symptomatology, etiology, and as much of its pathology has been ascertained are described, and Sir Joseph Fayrer

hopes that though long regarded as a dangerous and even a fatal complaint, it is amenable to treatment if properly and vigorously dealt with. The whole flux, says Sir Joseph, which has various symptoms, though not always directly related to any well marked form of climatic or malarial disease, is very insidious in its onset and progress, and very intractable if not early controlled. It is something more than ordinary diarrhœa, thought it often supervenes on that disease. In it the worse symptoms are often manifested, and a dangerous and protracted state of disease established, and it owes its fatality when continued beyond a certain stage to irreparable degeneration of the intestinal mucous membrane and glands, and the consequent inability to absorb nourishment. Death is due to anæmia and exhaustion from slow inanition, the channels for the admission of nutrient material being practically interrupted or destroyed. Sir Joseph thought this hill diarrhœa which affected dwellers in the hill stations, and the "white flux" of other parts of India, might be regarded as identical, while in some cases it was associated with, or often merged into, certain forms of chronic dysentery. The author considers it must be regarded as a climatic disease, though its etiological relations with malaria seem to be remote rather than direct. There is often a form of intermittent and irregular diarrhœa prone to attack people who return from India with hepatic and splenic derangement, which, though it may be the precursor of white flux, is not of so dangerous a character, and from which recovery is often so rapid as to show that it is due rather to functional disorder than to structural degeneration of the intestine. In summing up, Sir Joseph Fayrer says: "From the insidious character of this diarrhœa it often gains ground before radical measures are resorted to, and though a journey to Europe is a step in the right direction, much remains to be done. Diet, clothing, habits and mode of life are most important questions, and the whole object in view may be summed up in physiological rest." All irritating food must be avoided; milk alone (cow's milk) should be the only food, some three or four quarts taken daily, only a little at a time but often. No disease better illustrates the power of nature than this does. If perfect physiological rest be ensured, early repair rapidly takes place; if degenerative changes have gone too far, or if the diarrhœa be complicated with other diseases, the issue will probably prove fatal; but even in such cases amelioration may be procured; while in ordinary cases milk diet, if properly carried out, affords a reasonable prospect of recovery.

Brigade-Surgeon SCRINEN said he was convinced that the milk diet was not only the best but the only treatment to be relied upon. He mentioned a case of a gentleman who had suffered from the disease for three and a half years. He put himself upon a milk diet, and so soon as he did so the symptoms abated within a few days. Unfortunately, he could not be persuaded to adhere to the treatment, and so soon as he felt better, he insisted upon taking more substantial nourishment, always with the result of bringing back the symptoms. He ultimately succumbed from exhaustion. In another case, he also treated with milk, and five years afterwards when he saw the patient, he was so much changed for the better, he did not recognise him.—Dr. SANSOM said that they had had some cases of this kind at the London Hospital, and he was convinced of the value of milk treatment. He remembered that his colleague, Dr. Stephen Mackenzie, has seen great benefit derived from copious injections of nitrate of silver, a plan of treatment which was justified by the extensive intestinal ulcerations.—Dr. ANDERSON wished, also, to confirm the value of milk treatment, and asked Sir Joseph Fayrer whether he always gave it raw, or peptonised, or boiled.—Sir Joseph replied.

SOCIETY FOR THE STUDY OF INEBRIETY (Norman Kerr, president). **Treatment of Inebriate Women.**—Mrs. L'OSTE gave a summary of twenty-seven years experience in the treatment of cultured female inebriates. The "tapering off" had proved a failure, and immediate abstinence had been effectual and safe. At first both sexes were treated, but experience soon showed that homes for ladies and gentlemen should be separate. Inebriety was a disease often hereditary, and the germs frequently noticed in children. When not inherited, obstetric troubles were frequently the cause for the disease. She said fashionable pick-me-ups, reputed non-spirituous, but really intoxicating drinks, were often a cause. She did not think the people, when under the crave, were responsible for their actions. The predisposing cause was the first thing to combat. The disease was curable, and the patients should be encouraged to try and help themselves in effecting their own cure. Unconditional abstinence was absolutely essential, and from one to two years were generally required. The study of inebriety was making great strides, and there was great needs for governmental free homes for the indigent, who were often wrongly punished as criminals. Mrs. L'OSTE found that thirty per cent. were permanently cured, the patients having belonged to the cultured and wealthy class.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY (J. W. Martin, M.D., president). **Nervous Affection of Chronic Lead Poisoning.**—Dr. RUXTON read a paper on this subject. He considered that the type of epilepsy caused by lead poisoning did not differ from the usual character of discharge from the higher cerebral centres. He quoted a case of melancholia in support of insanity coming on only after vascular charges had been established, the man ultimately presenting unilateral convulsions before death, which were found to be due, it was thought, to pressure and irritation of the right pyramidal tract in the pons, the left side of which was completely broken up by a recent hæmorrhage.

Acute Peritonites.—Dr. HUNT read a paper advocating the treatment of acute peritonites by saline purgatives, showing that when this plan was adopted at the onset of the attack, the result was highly satisfactory.

Shawl Pin Passed per Anum.—Mr. C. MARTIN showed a shawl pin, two and a half inches long, which a woman had swallowed, and passed per anum after seventeen days-—Several specimens were shown by Mr. MAKEIG JONES.

* * * *

NEW YORK SURGICAL SOCIETY (Dr. Lewis A. Stimpson, president). **A Large Bursa over an Exostosis.**—Dr. MCBURNEY presented a specimen of exostosis removed from the outer aspect of the right femur of a young woman, over which a large bursa, holding three ounces of serum had been formed.—Dr. WEIR had removed such a bursa, and the minute extosis which had caused it, from a woman who had travelled all over Europe for the relief of what had been supposed to be a hysterical joint affection.

Operation for Dorsal Dislocation of the First Phalanx of the Index Finger.—The PRESIDENT showed a boy, eleven years old, who had suffered this dislocation in a fall upon the outstretched hand. All attempts at reduction by manipulation and traction having failed, he opened the joint by a longitudinal incision on its palmer aspect, and found that the obstacle to reduction had been created by the position of the anterior or glucoid ligament. This had been torn transversely close to its insertion upon the metacarpal bone, and the head of the latter had passed through the rent, and the torn edge of the ligament had been found tightly stretched across the dorsal surface of the metacarpal bone close behind the head. It had been so tense that it could not be lifted back with a tenaculum until after it had been nicked longitudinally at its centre. The wound had healed under a single dressing, and now, eighteen days since the accident, the motions of the joint were almost completely restored. He added that, in his experience, these dislocations of the index finger were even more difficult to reduce than the corresponding dislocations of the thumb, which were notoriously difficult.

Linen Thread for Sutures and Ligatures.—Dr. WILLY MEYER reported having found a substitute for other kinds of ligatures and sutures in linen thread, such as was sold at regular dry-goods shops. His experience with its use was only a short one, but confirmed the results obtained with the same article by Trendelenburg. It was serviceable, soft, cheap, and easily prepared. The only preparation necessary was to wind it on a glass rod, and soak it for twelve hours in a solution of corrosive sublimate (one per cent.), and then preserve it wound on a glass spool in a one to one-thousand solution of the same. Linen healed well in the wound, but it should only be used where primary union was to be expected. In comparison with catgut, its only disadvantage was that it was not so slippery, and had to be pulled well. When moist it was stronger than when dry.

* * * *

CLINICAL SOCIETY OF LONDON (Mr. Willet, president). **Traumatic Cerebral Hæmorrhage.**—Mr. HERBERT ALLINGHAM read notes on this case. Nathaniel C——, æt. forty, was admitted into the Great Northern Hospital. He had fallen off a tram-car when in a semi-drunken condition. When taken to the hospital he complained of pain in the left shoulder. There was no sign of external injury to the head. He slept well after a bromide and chloral draught. The next morning, December 8th, he complained of feeling drowsy, and headache on the right side of his head. His pupils were equal, but retracted to light. There were no signs of paralysis, no vomiting. December 13th.—He became more drowsy, not noticing things about him; his breathing was rather laboured and stertorous. At 6 a.m., December 14th, he had a convulsion. After the convulsion, the left arm and leg passed into a state of clonic spasm. The urine was 1020, no albumen, no sugar, and was passed unconsciously, but not during the fits. He had a recurrence of the fits at intervals. A week after the accident, I saw him, and determined to operate. Chloroform was given. A curved incision was made, ascending from the external

angular process to the molar process, and a large semi-lunal flap turned down, so as to expose the temporal muscle; this muscle was then divided from its organ and turned down. A crown of bone was then removed over the right fissure of Rolando—that is to say, about two and a half inches behind and one and a half above the external angular process. The posterior branch of the middle meningeal artery was exposed. The artery and dura mater were found to be intact, but the dura mater bulged, and did not pulsate. It was divided, together with the artery, and a large blood-clot was exposed, about three ounces of blood-clot were removed by the finger. On inserting the finger into the cavity, the brain was felt to be compressed. The pia mater was intact, except at the right frontal lobe, where the cerebral hemisphere was felt to be lacerated and soft. The cavity was well irrigated, until the solution 1-40 carbolic came out quite clear. One catgut suture was introduced into the dura mater, and two drainage tubes inserted into the chest. The edges were brought together with silk-worm gut sutures, and dressed with carbolic gauze. In three days after, the paralysis had gone, and on February 18th he left the hospital quite well.

* * * *

Odontological Society of Great Britain (Mr. Henry Senill, L.D.S., president). **Epithelioma Affecting the Upper Jaw.**—Mr. C. S. Tomes, F.R.C.S., read notes of this case. The disease affected the socket of a second upper molar, the tooth having undergone a considerable amount of treatment for some time. The roots were separated and screws inserted, whilst a ring surrounded the portion above the gum, and a contour crown surmounted this. The tooth remained quiet for eighteen months. Subsequently, on the tooth becoming less, it was taken out, when suspicious-looking granulations were found around it, and filling up the socket. Mr. Christopher Heath saw the case in consultation, and confirmed the diagnosis of epithelioma. Local treatment with zinc chloride paste having failed to eradicate the growth, excision of half of the maxilla was performed by Sir Joseph Lister. After three years, no recurrence had taken place.—The President drew attention to the loosening of the teeth, which was an early symptom in cancer of the antrum.—Mr. Weiss inquired whether patches of leucopatria were present in Mr. Tomes' patient, pointing out their diagnostic value.—The President showed a living specimen, in whom there was an extreme development of the lower jaw.—Mr. Jonathan Hutchinson remarked that the evidence was not so conclusive as to whether the growth of the bone was still active, although the tenderness which existed rather pointed to that conclusion. The case, to his mind, was very like a case he had under observation of the disease called acromegaly, in which the lower jaw, the digits, and the toes, all become enlarged. The head of this patient was particularly like, but as no apparent increase in size had occurred while under observation, it was acromegaly in an early stage. In osteitis deformans, although a similar overgrowth of the jaws occurred, the increase in size was not limited to these bones. It might be thought to be either congenital or acromegaly.

Surgical Diagnosis of the Teeth.—Mr. Jonathan Hutchinson read a paper on this subject, in the course of which he made a few remarks on the materials used for stopping teeth. Without for a moment disparaging amalgams as a stopping material, Mr. Hutchinson believed that in some rare instances they were the cause of intractable and irritable sores upon the lips, gums, and cheeks. He spoke simply as an observer, not knowing the chemical compositions of these stoppings, many of which he was told were secret preparations, but he had certainly seen ulcers which refused to yield to treatment disappear after the removal of discoloured amalgams. He had always been careful to eliminate the probability of roughness of the stopped teeth being the cause, and had never seen ulcers where good filling had been used. He quoted a case of an American physician, who presented a number of ulcers, which several surgeons had pronounced syphilitic. The patient, however, stoutly maintained that he never had syphilis, or a symptom of it, and all his children were perfectly healthy. Mr. Hutchinson ordered the removal of several amalgam filling he had inserted some years before in America, and the ulcers rapidly disappeared. Teeth affected by stomatitis, whether mercurial or otherwise, were often mistaken, said Mr. Hutchinson, for syphilitic teeth. Mercury given in infancy set up inflammation of the tooth sacs, and so led to deformity of the enamel. The test teeth in these cases are the first permanent molars, which might be compared with the premolars. Lamellar cataract, so commonly associated with stomatitic teeth, was due to convulsions. Speaking of dentition in rickets, Mr. Hutchinson deprecated speaking of any definite rachitic teeth. The disease attacked the teeth, as it did other structures. The value of considering the teeth lay in answering the question—not, are the teeth present? but rather, how and why did the teeth go? Mr. Hutchinson did not consider gout, as such, produced any typical teeth. As long ago as Graves tooth-grinding had been shown to be common among the gouty, and this practice led to wearing down the teeth. At the close of the paper there was an interesting discussion by the President, Mr. C. S. Tomes, Mr. Charles White, Mr. Storer Bennett, etc.

* * * *

British Gynæcological Society (Dr. Macan, president, in the chair). **Case of Erotic Feelings preceding and following Epilepsy.**—Dr. Routh read the notes of a case in which erotic symptoms preceded epilepsy. The patient was a lady whom he had first seen in 1874. She was then unmarried, and was suffering at that time from leucorrhœa, with ulceration of the cervix and follicular vaginitis, also dysmenorrhœa. She complained at times of something very much like fits. She was markedly hysterical. She had been addicted to habits of masturbation. She was now married, and had had three children. Since her marriage the fits had recurred, and sometimes followed conjugal relations. They were always stayed by valerian and the bromides. He read his notes on the case on October 18th. The catamenia had been unusually copious, but had lately been very irregular, and finally stopped, and headache and symptoms of confusion of intellect had followed. She was then forty-five. The uterus was very large, reaching above the umbilicus. The passage of a sound into the uterus was very painful, and brought on a fit. He ultimately decided to try the effects of the negative electric current to re-induce a menstrual flow, but on the occasion on which he did this she developed strong erotic symptoms, and had an epileptiform attack, after which she again became aggressively amorous to a lady to whose care she was for two hours consigned. The author pointed out that these were precisely the circumstances under which charges were made against medical men, and though his long-standing relations with this particular patient prevented anything of the kind, in that case it was evident that the situation was full of danger under other circumstances.

Dr. Hills said it would be a great advantage to fellow-practitioners if the details of this case be consigned in the "Transactions," so that it might be available on any future occasion.

Mr. Tait referred to the well-known case of Dr. Bradley. He said that it was important to notice the association of a certain form of epilepsy with an erotic condition. These things ought to be widely known. They ought to be in our text-books, and men should not be sent to prison on charges made by women who were very likely to be suffering from sexual disturbances of this kind. He added that another curious point was charges brought by children under the new law. He had been engaged by the police to investigate these cases, and in only one out of twenty or thirty was there reason to believe that such an offence had been committed.

Dr. Barnes said it was important that this case should be put on record, and mentioned a case in his own experience, insisting upon the necessity of inquiring into these statements very carefully.

Dr. Heywood Smith said that the relation of the electric current to the production of these feelings ought to be cleared up.

Mr. Tait said that one would like to know from authorities on epilepsy how far the erotic excitement was the cause of the epilepsy?

Dr. Heywood Smith pointed out that in the case he had just brought forward, the patient had no fits before marriage, but afterwards had seven or eight in a day.

Dr. Bedford Fenwick insisted upon the importance of remembering the connection that existed between erethism and mental trouble.

Dr. Purcell asked whether there was any epileptic history in Dr. Routh's patient?

The President said the application of the current to the interior of the uterus was not likely to give rise to erotic feelings. The cervix was sensitive, and that might be protected. He asked whether the woman in Dr. Routh's case had expressed the opinion that liberties had been taken with her. He thought that gynæcologists were in a better position than most ordinary practitioners since patients came to them expressly for the purpose of having their reproductive organs examined.

Dr. R. T. Smith said he had been consulted only that week in reference to a young lady, æt. twenty-three, who had had fits consequent on masturbation.

Dr. Routh, in reply, said his only object in bringing the case before the Society was to place on record a well authenticated case in which erotic symptoms preceded and followed epileptoid attacks. It was for the same reason that he read his paper on "Nymphomania" in order to show the absurdity of certain charges made. He observed that even an ordinary vaginal examination was sufficient in some women to provoke the sexual organs, therefore it would not apply to electricity

only. The patient had not accused him of having taken liberties, but she had retained her impressions, and had expressly authorised him to publish the case because she felt that other people under similar circumstances might bring a charge against medical men.

* * * *

ROYAL ACADEMY OF MEDICINE, IRELAND (Dr. Byrne, president). *Obstetrical Section*—Dr. GRAVES exhibited for the President, who was absent, a **Sloughing Fibroid.** It was removed from a woman by an operation at which he (Dr. Graves) was present. The peritoneum was very thick, and the tumour came down upon the uterus. A pint of pus came from it. There was a mass of malignant growth, and also a great many adhesions in the abdomen. The women died.

Dr. CRANNY moved—"That the marked sympathy of the Section be conveyed to the family of the late Dr. George Johnson, one of the former Presidents of the Section." Dr. Johnston had been Master of the Rotunda Hospital, and had given them all a great deal of valuable information in his reports connected with that institution. The resolution was passed in solemn silence.

Laparotomy for a Ruptured Tubal Gestation.—Dr. THORNLEY STOKER read the particulars of a case in which he had performed laparotomy for a ruptured tubal gestation. The woman, who was twenty-four years of age, and who had been four years married, had the usual history of previous tubal disorder and pain on the left side—that on which the gestation had taken place. She had given birth to a still-born fœtus at the seventh month during the year following her marriage, and had not since been pregnant. The rupture took place about the twelth week. The case, unfortunately, did not come under his care until the eighth day after the rupture, when the woman was so exhausted by peritonitis, pain and vomiting, that operation was undertaken as a forlorn hope, with the result of death about eight hours afterwards. The case had been regarded, before he saw it, as one of intestinal obstruction. There was a broad-ligament hæmatocele in the tube, as large as a hen's egg, and an enormous extravasation of blood into the peritoneum. The former was primary and the latter secondary, and probably due to the penetration into the peritoneum of the vessels of the placenta. The ovum, with the exception of the placenta, had perished at the time of the first hæmorrhage, and growth of the placenta had resulted in the fatal bleeding. The portion of the broad ligament containing the remains of the gestation was ligatured and removed, the peritoneum washed of clots and fluid blood, and the intestines, as far as possible, freed from the extensive adhesions which existed. The gestation had taken place in the tube near to the fimbriated end. He pointed to two matters of exceptional interest in the case—one that it constituted an example of the rare condition of a primary broad ligament hæmatocele, followed by a secondary intra-peritoneal one. He explained his view that the latter was not due to a rupture of the former, but to a growth and penetration of the vessels of the surviving placenta. The second exceptional feature was the rectal obstruction, due to the intra-peritoneal pressure from clots. This he called attention to as disproving the statement of Mr. Tait, that rectal obstruction is necessarily a sign of extra-peritoneal hæmatocele. He referred to the brilliant results obtained by operation in these cases by Mr. Lawson Tait, whose views as to the propriety of operation he strongly advocated.

Dr. BYRNE said the case was a remarkably interesting and instructive one. One feature in it was the difficulty of diagnosis owing to the simulation of the symptoms of obstruction of the bowels caused by the large quantity of blood that was poured into the peritoneum. He supposed one of the reasons why cases of rupture in ectopic gestation had not been oftener noticed by writers was that when a large effusion of blood took place into the peritoneum the patient generally died. Dr. Stoker had not mentioned whether in his case any trace of the fœtus was found. There was no doubt that the treatment adopted by Dr. Stoker in his case was right. If they were convinced that there was effusion of blood into the peritoneum they should perform laparotomy, remove the clots, tie the vessels, and give the woman a chance. The difficulty was to determine the exact moment at which they should perform laparotomy, for generally there was such collapse that their hands were tied. Whether a correct diagnosis were arrived at or not he thought that symptoms of obstruction alone would justify the operation. It was an interesting question as to what caused the obstruction of the tube in the present case, and why the fœtus should have developed at the particular place where it did.

Dr. HORNE said they were deeply indebted to Dr. Stoker for this interesting and accurately described case. It was extremely interesting from a medico-legal point of view. There was a woman brought to hospital without any account of previous history, and having well-marked symptoms which might have been taken for poisoning. The diagnosis that seemed to have been actually made was intestinal obstruction. From the specimen exhibited he felt a difficulty in arriving at the conclusion that the intestinal obstruction was the result of the hæmorrhage, and having gone into the free cavity of the peritoneum he failed to see how the pressure of the clots could have obstructed the intestine. The history of the case looked very much as if the woman had had syphilis and disease of the fallopian tnbe, which would account for the impregnation taking place in the tube itself. The period at which the rupture took place, corresponding to the thirteenth week of pregnancy, was the usual time at which such ruptures occurred; they rarely happened later than the fourteenth.

Dr. O'CALLAGHAN said they had not seen any operations for cases of this sort in Ireland, and he thought that the cases must have been overlooked, for in England Dr. Lawson Tait had published a great many of them.

Dr. MACAN said during six years' experience in the Rotunda he had seen a great many cases of extra-uterine fœtation, with hæmorrhage, and he had never operated in any case while the hæmorrhage was taking place. They had three cases under observation at the same time, in which, as far as they could observe, ectopic gestation had taken place. Of the total number of cases, some have made a good recovery, and some had not; and there were others under observation at present. Ordinarily speaking, he would not dream of operating in any case unless he diagnosed it early before the rupture. Once the rupture took place they had hæmorrhage into the peritoneum: and then the question of operation or not became a most difficult one to decide. As ounce after ounce of blood passed the bleeding lessened; and once it stopped the woman was almost cured. Hæmorrhage into the peritoneum was taken up with great rapidity. If meddled with it became a different thing. With a view to operation the thing would be ascertained before any rupture took place; after a rupture it was extremely difficult to decide on the moment to operate. When the hæmorrhage was retro-peritoneal the woman would very likely get well without any operation. He believed that numerous cases of extra-uterine fœtation occurred and got well without any doctor seeing them at all.

Dr. STOKER, in reply, said he had mentioned that in his case the fœtus had become broken up, and the remains lay among the clots in the tube and could not be identified, but the placenta could be readily seen, and its attachments studied as it had survived the destruction of the rest of the embryo. He himself had not regarded the case as one of intestinal obstruction; what he said was that it had been so treated before it came under his observation. In fact he had not enough evidence to prove what it was. The only thing he knew for certain was that the woman was dying of some intra-peritoneal condition that required laparotomy for its accurate diagnosis. In his paper he (Dr. Stoker) distinguished between extra-peritoneal bleeding, where the blood coagulated and dried up, and bleeding into the peritoneum. In the former cases an operation was not always called for, and the woman might make a perfect recovery without it. In the latter, where the sac of the peritoneum became a great mass of blood and clots, and the woman was dying from loss of blood, there should be no hesitation about operating. Dr. Tait had published forty-one cases of intra-peritoneal hæmorrhage in which he operated, and saved thirty-nine. He could not conceive a surgeon making the statements that Dr. Macan had made—viz., that it was easy to diagnose ectopic gestation, and that even where intra-peritoneal hæmorrhage had occurred he opposed the operation of laparotomy.

AMERICAN NOTES.

FROM A CORRESPONDENT.

DIPHTHERIA is prevalent everywhere. The following report may interest your English readers. Dr. H. Jackson, of Boston, introduced the subject at the Massachusetts Medical Society, at its last meeting, January 29th:—

Notes on Twenty-seven Cases of Diphtheria, occurring between July 1st, 1888, and January 1st, 1889.[1] By HENRY JACKSON, M.D., of Boston.—From July 1st, 1888, to January 1st, 1889, I treated twenty-seven cases of diphtheria out of 1,031 cases of all kinds, seen in the second district of the Boston Dispensary, situated on the west side of Hanover-street. Of these cases, five died; four of septicæmia, one of laryngeal obstruction. Five cases were very mild; two were not confined to the bed. In most of the cases the membrane was confined to the uvula and pillars of the pharynx. In these cases a

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene, of the Suffolk District Medical Society, January 29th, 1889.

large part of the roof of the mouth and lips was covered with membrane. Fifteen cases occurred in houses where the sanitary condition was bad; ten cases where the sanitary condition was apparently good; two cases in a house that seems to be in good condition; and yet one where I have found much sickness in the last two years, notably diphtheria last winter. Where there were several children in a family, usually one or more cases of diphtheria appeared shortly after the first cases—namely, in a family of three children all had the disease; in a family of five children four had the disease; in a family of three children two had the disease (later in the year two members of this family had typhoid fever). In all cases the disease was strictly confined to the house where it first appeared, and in only one instance did the disease spread to other families living in the same tenement. Of the twenty-seven cases, four were young adults; the average age of the children was five years, the youngest being eighteen months.

As of importance in making an early differential diagnosis between diphtheria and follicular tonsilitis, I have found that in diphtheria (1) the temperature was much lower, often normal; (2) the constitutional symptoms were usually less severe at first; (3) the glands about the neck were more swollen and tender. In all cases I have felt justified in making a diagnosis of diphtheria where there was membrane on the uvula or on the pillars of the pharynx. As last year I could report that, having had in my charge in this district a large epidemic of scarlet fever, I was not aware of having carried the disease to a single child, so this year not a case of diphtheria has occurred in a family that was under my care for other diseases. In other words, so far as an opinion can be formulated from so small a number of cases, the disease is very infectious to young children brought into immediate contact with those sick; the disease does not spread from house to house; the disease is not easily carried by a third person. The following list shows the character and distribution of the various infectious diseases in the portion of the city above described, during like periods of two successive years:

JULY, 1887, TO JANUARY, 1888.

Diphtheria	8
Tonsilitis	57
Scarlet Fever	68
Measles	5
Typhoid	24

JULY, 1888, TO JANUARY, 1889.

Diphtheria	27
Tonsilitis	33
Measles	5
Scarlet Fever	1
Typhoid	23

Dr. A. L. MASON opened a discussion on diphtheria with a report of six fatal cases of that disease in adults which had recently occurred in the new diphtheria ward at the Boston City Hospital. This ward, which was opened in April, 1888, was stated to be admirably adapted to its purpose, and the nursing was, in the experience of the reader, unequalled, because he knew of no other hospital in this vicinity where the nurses are systematically trained to take care of large numbers of diphtheria patients, a duty which they perform with the greatest intelligence and devotion. Under these favourable conditions for treatment, however, the mortality had been large—many patients, both adults and children, dying from septic poisoning, heart failure in convalescence, and tracheal obstructions. Their state at entrance was often very bad, sometimes moribund. Almost all cases admitted would be classed as severe.

Dr. Mason continued as follows: It will be well, then, to consider how fast this disease has grown upon us, from a few isolated cases thirty years ago, until it is now the most fatal endemic disease of a preventable nature which we have to contend with. The success of our board of health with smallpox makes it proper to assume that the mortality from all infectious diseases could be reduced to a minimum if similar methods could be adopted for their suppression. In this connection I will refer to the report of the Glasgow Fever Hospital, where by isolation and disinfection an improvement in the public health has been obtained. There are obvious reasons why it is difficult to deal with diphtheria in this community, at present at least, in as summary a manner as with small-pox, although diphtheria is much less contagious, therefore more readily controlled; it is also more fatal, and in many cases it is entirely beyond the reach of medical or surgical aid. During 1888 the number of deaths from diphtheria in Boston was 470, one-third of all the cases reported. This is in excess of the whole number of deaths from yellow fever in Florida during the recent epidemic, in which there were about 350 deaths in less than 4,000 cases, 9 per cent. At the city hospital, with the assistance of Dr. W. A. Morrison, house-physician, I have found that the records of the diphtheria wards show in 1888 the admission of 199 medical patients and 126 surgical—total, 325; 34 cases were transferred from the medical to the surgical department for operation on account of tracheal obstruction. It will be seen then, that 160 patients, or nearly half the whole number admitted, required surgical treatment. Of the remaining 165 who were treated medically 47 died, or 28 per cent. Under 15 years of age there were 145 admissions with 40 deaths, 27 per cent. Between 15 and 30 years, 6 deaths out of 49 cases, 12 per cent. There were but five patients over 30 years of age—viz., one of 30, one of 31, two of 34, and one of 40 years. One died from tracheal obstruction, which was not relieved by tracheotomy. Direct contagion was reported in about one-fifth of the admissions, but the history in this respect is often deficient. Many of the worst cases come from among the Germans, Poles, Italians, and other foreigners. Two cases came from the same family in six instances; three cases, three times; four cases, three times; five cases, once. Thirty-eight cases from thirteen families. Among the inmates of the hospital who took the disease were one of the house-physicians, as previously mentioned, who died after a brief illness; three nurses employed in the diphtheria wards; one nurse in a distant ward, and one laundry maid; all of whom recovered. In 1880, when the facilities for isolation were imperfect, there were but seventy-one admissions to the medical department, of whom seven were hospital employees; 22 per cent. of cases died. In 1887 the rate of mortality, exclusive of surgical cases, was 29 per cent. It is probable that a large proportion of the gravest cases occurring in the city came to the hospital, especially for tracheotomy. This necessarily makes a high death-rate; forty-seven per cent. out of a total of all cases admitted in 1877, 184 in number.

Dr. G. H. LYMAN said the number of cases of diphtheria has certainly been very startling at the City Hospital, and they presented some features unlike those I have observed in former years. Since October 1st I think there have been under my service thirty cases; eight of these were transferred for operation, leaving twenty-two cases, of whom four died. There has been another feature in connection with these cases that, I think, has been very striking, and that is the very weak pulse and the low condition of the patient in almost all the cases that I have noticed, certainly in a very large number. Out of these twenty-two cases there were four of distinct heart failure. One of them recovered; the other three died, and died apparently from a paralysis of the heart. It was not thrombosis; they died easily, quite suddenly; there was no considerable effort required for breathing, no sudden excitement towards the last, which, I suppose, we should look for in cases of thrombosis. With the exception of these cardiac failures there have been none of the cases followed by any symptoms of paralysis elsewhere. In cases of typhoid fever we have had quite a number of patients recover apparently entirely from the typhoid, but we found several of them suffering from neuritis. I have half a dozen cases of neuritis following typhoid fever, but none following diphtheria.

The great prevalence of the disease, it seems to me, is a thing to which prompt attention should be given. I cannot think, in view of the statistics of the Glasgow Hospital reports, that it is a necessary disease. It seems to me something could be done to check it. We can check small-pox; Glasgow people seem to be able to check diphtheria. I see no reason why we cannot do it here as well. The Boston City Hospital has accommodation for twenty-five to thirty diphtheria patients. For a portion of the time the ward has been fairly full, I don't think so full that any cases have been obliged to be placed elsewhere. The cases Dr. Jackson speaks of, of mild diphtheria, or, granting a doubtful diagnosis, follicular tonsillitis, have been quite numerous. We have had a good many cases in which, for twenty-four hours, we did not attempt to make a positive diagnosis. There seems to have been a more constant accompaniment of tonsillar inflammation, distinct from diphtheritic disease, than I have ever noticed before. A good many have turned out to be tonsilitis, but some of them undoubtedly were diphtheria. The importance of the thing, it seems to me, must be manifest to this society, but I do not know how we are going to remedy it except through some action of the Board of Health. I think the subject is important enough for this society to appoint a committee to consult with the Board of Health to see if there is not something to be done to check the spread of this disease. Dr. Jackson mentioned one point that was confirmatory of the general views on the subject; that the disease was decidedly infectious, and *not* contagious. I have always supposed that to be the case, but his statistics and those which the chairman has given bear out my opinion very strongly. I am rather surprised at the great mortality that the statistics which have been presented give. I did not suppose, from my experience on the medical side of the hospital, that it was anything like that. I suppose the cases turned over to the surgical side were transferred too late, or were of such a character that no operation would relieve the patient. This would increase the general operation very much. The operation in a

large number of surgical cases—cases extending to the larynx and requiring operation—is done in patients already reduced by the disease, and the mortality is very large indeed. Putting these aside, I should say the mortality of diphtheria was small.

Dr. DURGIN, Chairman of the City Board of Health: The appointment of a committee would please me very much. I have listened to the remarks with a good deal of interest, and I felt very greatly pleased when I understood that there was to be a portion of this evening taken up with the discussion of the prevalance of diphtheria in Boston. The cause of such a large nnmber being treated at the City Hospitals has already been given by the reader. The accommodations have been greatly increased in the past year and, in addition to that, the Board of Health have taken measures to send more patients there than ever before, in consequence of the increased accomodations. I have been somewhat surprised at the very large rate of mortality at the hospital, which undoubtedly is accounted for in a large measure by the fact that the *worst cases* come there; not all, but many of the worst cases, and particularly the surgical cases. The mortality for the whole city, however, has not increased this year; that is, the rate of mortality, the average percentage of mortality of the whole number of cases reported. I have brought in a transcript from the records to show the percentage of mortality of the number of cases reported for the last eleven years; that is, during the period over which we have called for reports from the physicians. I find that the percentage of deaths from diphtheria of the total numbers of cases reported for the past year was 33.18 per cent., and for the past five years the percentage has been 29.16 per cent. against 33.56 per cent. for the previous five years; there having been, as you see, quite a reduction in the percentage of deaths in the total number of cases reported in the last five years compared with the previous five years.

In 1878 we called for reports upon diphtheria, and the first year we received 1,370 reports, with 448 deaths, giving a percentage of 32.7 per cent. for the deaths. For the first five years there were 7,363 cases, and in the last five years 6,134. I wanted to say in this connection that the difference between the official treatment of diphtheria as contrasted with small-pox is certainly very great. In small-pox we have older people to deal with; the average age is considerably higher than with diphtheria, there is therefore less trouble in separating children from parents. In small-pox there is very great fear of the contagion; with diphtheria it is not as great. People will expose themselves and allow others to expose themselves to the one when they would avoid the other. A still greater difference between the two diseases is in the matter of diagnosis. In small-pox it is very easy, and is almost always made at a very early stage. The physician either recognizes the disease himself at once, or calls an expert to make the diagnosis. In diphtheria it is not so. In diphtheria there is, as we know, oftentimes great difficulty in making a positive diagnosis. The child remains under suspicion for several days if not weeks, therefore the report to the Board of Health is delayed, sometimes until the child has died, and allows the consequent exposure more or less of other children to this disease, both to the family and to people who are liable to call at the house. Another difficulty in the way of treading diphtheria is the difference of opinion in the profession in regard to the true character of croup. There is a queston in the Society as to whether croup and diphtheria are one and the same disease, and so long as that difference of opinion exists, so long we shall have a large number of cases of a contagious disease, call it what you may, that will spread from one person to another, and cause croup in our community. The cases are numerous where the disease has spread from one person to another in a family, and beyond the family, while the physician has persisted in calling it croup, and therefore not contagious. Another difficulty which stands in the way of successful treatment by isolation of diphtheria is the fact that in Boston we have no adequate hospital accommodation, notwithstanding the fact that the city has been somewhat generous in providing greater facilities in the past year; and the accommodations, I trust, have not been used to their utmost capacity yet; still, we are constantly running across families where it is almost impossible to separate the children from the parents, or from each other, and the patients remains at home, and thus we constantly have a very large number of points of infection through the city, which never exists with small-pox, and which we cannot overcome. It becomes absolutely necessary, if we would treat diphtheria as we do small-pox, that the Board of Health shall have some place to quarantine such a family, in order to disinfect the house. Again, with small-pox, we have the great advantage of vaccination, which cannot be overrated. There are, in spite of the best we can do, some insurmountable obstacles in the way of treating diphtheria and reducing its prevalence in our city as we might do with small-pox.

Dr. GEORGE B. SHATTUCK. We are very grateful to Dr. Mason for bringing before us such a practical subject in such a practical way; and it is only by discussing such a subject in meeting, as we are doing to-night, that we can make some approaches towards creating precisely that public opinion which Dr. Durgin appeals to as necessary for the support of an executive body like the Board of Health; for it is very certain that a Board of Health is limited in its action, first of all by the powers which the laws give it, and secondly, beyond that, by the condition of public opinion even where the laws support it in active procedures; and our expectations in regard to what the Board of Health can do must be controlled, even beyond and outside of what the laws allow, by the condition of public opinion, which limits what the Board of Health can practically accomplish. I think there is a great deal in the point Dr. Durgin has made with reference to the difference between diphtheria and small-pox. There is an utterly different feeling in the community with reference to small-pox, and one comes across it in all sorts of ways. I remember in a trial in court with reference to typhoid fever, it was perfectly simple to convince the jury and the judge that you could not have a case of small-pox without a preceding case, but as soon as we attempted to tell them they could not have a case of typhoid fever without a preceding case, that seemed to them very extraordinary, a very singular theory indeed, and they immediately wanted to know, if that was so, where the first case came from. With reference to small-pox that difficulty never came to their minds. The public does not reason about these diseases, and you can't do with reference to diphtheria what you do with reference to small-pox.

There is the question of diagnosis. Among some of our brethren who practise medicine, and especially sectarian medicine, a single individual may have three or four hundred cases of diphtheria in his practice in the course of a year, and of this probably the mortality will be absolutely nothing. I remember such an instance not long ago in Springfield, where a distinguished sectarian practitioner described to a society how he had had several hundred cases of diphtheria in the course of the preceding year without any deaths whatever. One of the society, who had taken pains to look up the returns at the registrar's office, showed him and the society that he was mistaken in regard to this. But, of course, the question of diagnosis is a very difficult one, and cases may be returned as diphtheria which are not diphtheria, and on the other hand, it is perfectly easy to conceal such a disease as diphtheria, which has not any external manifestations. Whilst acknowledging all that, I still sympathize with the feelings which the chairman has expressed; and I think any one on duty at the City Hospital, where we have certainly an opportunity to see as much genuine and serious diphtheria as any other practitioners in this community, if not more, could not help wishing that something could be done. In some cases you cannot force patients to be isolated. I remember one of those unfortunate instances in which almost the whole family—the mother, a child at the breast, and two or three yonng children—were all brought to the hospital with diphtheria, and one of the children, I think, died; the father came and took the rest of the family away and took them home against every remonstrance. It does seem as though such a thing as that ought not to be allowed to occur. The father took them back to the same house in which diphtheria had occurred a certain length of time before they had inhabited it, and he took them back there because, he said, he couldn't go anywhere else. He made an effort to get other lodgings, and it was known his family had had diphtheria, and he was driven back to the same lodgings. Such things are constantly presenting themselves to our attention, and necessarily make us desire, if possible, that something might be done.

With reference to the mortality at the City Hospital, I don't think it is a large mortality, as mortality from diphtheria is recognised. I think that the statistics of the text-books and of other hospitals will show that the mortality is expected to range rather above 30 per cent. than below it. Many of the cases at the City Hospital are not only the worst cases, but are also, many of them, in the worst possible condition; and I think that it is rather surprising that under these circumstances the mortality should be as small as it is. Without going into the question of treatment I should like to say that, for many years, I have felt that the fact that the mortality has been kept at the point where it has been largely owing to the extremely skilful and faithful nursing which these patients receive at the City Hospital. I don't believe that that class of diphtheria cases would stand anything like as good a chance anywhere else under other circumstances, and for such cases as these, whilst it is important to have a sensible and experienced physician, I cannot help feeling that it is of fully equal importance to have an intelligent, and faithful, and devoted nurse, who is always on hand to carry out the minutest directions in the most prompt, and regular, and efficient fashion.

Dr. G. H. M. ROWE, Superintendent of Boston City Hospital. This is a subject in which I am much interested, as it involves so much experience in regard to the care of the patients with diphtheria at the City Hospital. The Board of Health for several years have appealed to us for greater facilities for the care of patients with contagious diseases.

The same thing has been done in the City Hospital Report, in the Trustees' Report, and in the Superintentents's Report, for at least seven years previous to the time when we received our appropriation. Formerly these patients were taken care of in the mixed wards called K and L. The mortality was thought then to be large. The number of nurses who contracted diphtheria was very much larger then than it has been since the new wards were erected. It was only by publishing openly in the City Council the fact that patients had come in there with one disease and contracted another—nine cases in one winter, of whom four died—that the appropriation was gained. I think it is an open question whether diphtheria wards should be attached to a city hospital; but it was Hobson's choice at that time. The Glasgow Hospital, which has been alluded to by Dr. Mason, is, as far as my knowledge goes, the finest hospital in the world, and the regulations for the separation and isolation of contagious diseases are the best I know of—rules we are not able to enforce at the City Hospital. Our new wards, of course, were experimental in a large measure, but experiments have proved that they are eminently successful in heating and ventilation. There is one fault which could be remedied, and that is that the fresh air supply is not equal to the exit. The system of ventilation is such that fetid odours are carried off rapidly. The accommodations have never been filled to their utmost capacity. We have accommodations for forty-two patients with diphtheria. At no time have there been more than twenty-seven, and it is rare that there are above twenty-two. In previous years the Board of Health has been clamouring for a place to carry these patients. The city government through its Council has supplied such a place, and yet it appears from statistics which are well known to the gentlemen connected with the hospital, that the mortality this year has been something that is, I may say, alarming. It is so much so, and recognised at the hospital to such a degree, that the nurses, although very anxious to see the result of the experiment, become depressed after they get into these wards, and are glad to be relieved and sent elsewhere. They work with the utmost faithfulness, and yet, patients who seem to be doing well often die suddenly from septic symptoms or heart failure. That has a very depressing influence upon the nurses. During the last week in November Dr. Prescott made some statistics. They are not made with reference to publication. They are very nearly the same as those by Dr. Mason. The total number of patients with diphtheria admitted this year was 337. Dr. Mason has given the statistics of the patients admitted on the medical side. I have those who were admitted on the surgical side up to about the 5th or 6th of December. To that date the total cases admitted on the surgical side was 139. Out of that number the deaths were as follows: Tracheotomy was done in thirty-five; of that number, five recovered and thirty died. Intubations, seventy-one; fifty-four died and seventeen recovered. By another classification, of those cases on whom intubation was first done, and subsequently tracheotomy, comprising sixteen cases, all died. Out of seventeen cases on whom no operation was done, for various reasons—mostly because they were septic, and operation deemed useless—four recovered and thirteen died. That makes a total of eighty-seven deaths. The total deaths were 53 per cent. at that time. The total admissions to the City Hospital in five years have been 960; in four out of five years 333 cases have died. When the new wards were opened, I sent a communication to the trustees, recommending certain rules in regard to the isolation of cases and to the limitation of visitors. It was decided that the practice of admitting friends should go on in a tentative way, and the attempt be made to limit them as far as possible. Practice has shown that what Dr. Durgin says holds true: it is almost impossible to shut out the parents from their children; and if any attempt of that sort is made, they immediately take their child away. One invariable rule is that patients with tracheotomies and intubations are considered as *dangerously* ill. The parents are admitted at all times before eight o'clock in the evening. We are practically able to exclude all friends except the parents, but beyond that, it is very difficult to go in wards attached to the hospital; it is only possible when we have them isolated and separated. The only way to bring this about has been intimated by Drs. Lyman, Shuttuck, and others, and that is the creation of public opinion. If the Board of Health cannot do it by its rules and regulations, and by expression of opinion through their reports, and in other various ways; if the City Hospital, through its annual report, and that of the superintendent and trustees, are not able to accomplish it—the only way out of it would seem to be that the profession, through its societies, in some formal way should try to educate the people to a better state of public opinion. A conference with the Board of Health has been suggested. Until public opinion is created, so that it shall influence the uneducated classes, and until some such legal restrictions are made for diphtheria as for small-pox, it seems to me impossible to stop it. When that period is reached, it seems to me that a great deal will be accomplished in reducing the mortality, and also in reducing the amount of disease. At the present time there are eighteen or nineteen cases of diphtheria at the City Hospital. The ward for scarlet fever has been closed, with the exception of two cases, for nearly three months.

Dr. C. F. WITHINGTON: My experience of diphtheria, so far as hospital work is concerned, is limited to the out-patient department of the City Hospital; and I am sorry to say that patients with diphtheria come there, and it is not an infrequent occurrence to find, in looking over the patients in the morning, that a patient with diphtheria has been sitting in immediate contact with other patients in the waiting-room. That, I suppose, is not peculiar to the City Hospital out-patient department. The same must necessarily happen more or less in all outside clinics. It is to be hoped that when the new building is completed at the City Hospital, some opportunities will be found to question patients, at least sufficiently to indicate the possible existence, not only of diphtheria, but of other eruptive diseases, so that these patients can be removed from contact with the others.

A question which has been of a good deal of interest to me of late has been with reference to the comparative frequency of diphtheria in the various wards of the city. I would like to know if the records at the Board of Health's office show the distribution as to the wards of the city; because, it seems to me, that it is a matter of considerable importance. It is generally assumed that a great deal of the diphtheria comes from the North End districts, and other more crowded portions of the city. In Roxbury there is considerable prevalence of diphtheria for the last year. One of the cases reported—Case 3—I saw before she entered the hospital. Her surroundings were certainly not such as to give any clue to the origin of the disease in her case. In one house in that district, apparently in perfect sanitary condition, a well-built, large house, in 1876 there was a case of diphtheria in a woman of sixty or upwards, who died. The family then moved away. Two years later a young woman was confined in the house, and died of puerperal fever. Her servant went home with a sore throat, which was serious, and whether she recovered from it I do not know. A sister of the lady sick with puerperal fever went home and developed typhoid fever; she was seriously ill. Another family took the house for a year or two, and in 1880 another case of diphtheria occurred in the same house in a child. Last summer a lecture was published in the *Boston Medical Journal* in regard to the relative frequency of diphtheria in urban and suburban communities. The conclusion was drawn from some fifty different outbreaks of diphtheria, mostly in suburban communities, that in a pretty large number of cases of diphtheria it was impossible to trace the first case of the epidemic from a previous case. In only four out of fifty could the writer trace the first case from a previous case of diphtheria, and that he was inclined to believe that a certain number of cases of diphtheria may develop from general insanitary conditions, possibly irrespective of a specific contagion from a previous case. That evidence was tolerably strong in his cases. He cites a number of parishes of over 1,000 inhabitants which had a small number of cases of diphtheria in this period of years, while in another series of smaller parishes the frequency of outbreaks was proportionately large. The figures he gives seems to me not to be borne out altogether by the figures in this country, so far as I have been able to ascertain. The last monthly report of the New York State Board of Health, for instance, gives the frequency of the deaths from diphtheria for the month of November, 1888, in the different districts of the State, and of course the mortality by direct conveyance of disease from one to another would naturally be expected to be greater in the cities, but in spite of the fact that treatment is more active there than in the country districts, the preponderance was greater in cities like Brooklyn, and Albany, and Troy, than in the black-country districts; whereas, the report of Dr. Barnes just referred to gives a much larger number of occurrences in the remote districts than in the larger cities. I should like particularly to know whether the occurrence of diphtheria is very much greater in the wards in this city which approximate more nearly the country conditions than in the more crowded wards, or the reverse.

Dr. DURGIN: I cannot reply with exactness; but in the past year the distribution has been scattered over the entire city much more than in any previous years. As a matter of guess-work, I believe that the percentage of cases of diphtheria in the population of the out-lying districts is rather greater than that in the more densely populated parts of the city. I think that Dr. McCollom could give a better opinion upon that subject than I, because he sees more of the cases. Dr. McCollom and his assistants usually see most of the cases, particularly those in the central part of the city. I would like to call attention to one or two points in relation to this disease, and one is the repetition of the disease in the same patient. The text-books, I think, say that one attack seems to predispose the patient to subsequent attacks. Although my own personal experience has not been a large one, this statement of the text-books has not been borne out by my observation; and I have fallen in with very few physicians who have found that that was true. We

occasionally hear a patient say that she or he has had diphtheria several times before. Of course that is partial evidence. I know that some physicians have seen a second and perhaps a third attack in the same patient. Of course, if this is largely true, it gives us a much less advantage in taking care of diphtheria than in taking care of most of the other contagious diseases. I should be glad to hear expressions of others who have had experience with diphtheria on that point.

The matter of removing a patient with diphtheria from the City Hospital is a serious one. Legally, I think, neither the trustees nor the Board of Health would have the right to retain such a patient contrary to his desire.

Dr. ROWE: Of course we adapt our policy to the class of people we have to deal with. In a large number of cases we have dissuaded them from removing patients with this disease. In all cases where such people remove them they are discharged as going on their own request and against advice. We have a printed form for such cases, and at the end we state that they remove their child or friend, knowing the disease to be diphtheria and dangerous both to the patient and the public, and they take the entire responsibility, freeing the hospital and its physicians and the authorities from all responsibility. There is a certain more ignorant class to whom we say, "It is impossible to take your child away." We say it to the Poles and Huns. "You cannot do it without permit from the Board of Health." If we should make it a test case there might not be sufficient power with the Board of Trustees to retain a given case. If patients are taken from the City Hospital it should be understood that it is not done until after measures are used, some of which are fair, and some, perhaps, not quite truthful, with the more ignorant classes, to retain them.

Dr. G. B. SHATTUCK: I should be sorry if any gentleman present got the idea from anything I said, that I supposed, or meant to indicate that there was any power vested in the City Hospital or its board of trustees to prevent such an occurrence. I cited the occurrence to indicate to the society the position of public opinion, and the difficulties in dealing with this question, where such a thing as this was possible and legal, and could be done, and could not be prevented; and it is exactly one of those points which we want to educate public opinion to deal with, and to stimulate our lawmakers to make laws with regard to. With reference to the family I cited, the father there was a very independent, intelligent New Englander. If he had been a Pole or Polish Jew, or German or Austrian, then, as Dr. Rowe says, there would have been some hopes of dealing with him, because he is used to a paternal form of government. It is difficult to make our diagnosis in many of these cases. Then as soon as we have made our diagnosis, it is a pity we have not the power, by law or public opinion, to isolate our patients.

Dr. DURGIN: In a case of small-pox we never take a child without its mother or sister with it if possible, and that generally constitutes all the visiting allowed in the hospital. In very few instances the mother has been allowed to come to the hospital after the child has been removed to the hospital, but is always retained until the anxiety is over, and then thoroughly disinfected and carried home. I don't think that the City Hospital trustees or the superintendent can be held to blame at all for the withdrawing of the patient. I don't understand that they have any legal right to retain them.

Dr. G. H. LYMAN: I should like to ask the law on that point; if the law gives the board of health the power to isolate a small-pox case, why should it not have the right to isolate a case of diphtheria?

Dr. DURGIN: It has the same right.

Dr. LYMAN: These patients come in by order of the board of health; ought not they to be retained until the board of health gives permission to have them removed?

Dr. DURGIN: I don't understand that the board of health has control over a patient after entering the City Hospital. We have the power to start them for the hospital, but no control after they are in it, the hospital not being in charge of the board. The line where our authority begins and ceases in that case is not quite clear. I can only say that when we have left the patient in the charge of the officers of the City Hospital I don't understand that we legally have any further right, can exercise any further right, can exercise any further control over him. In our own hospital—one established and maintained by ourselves—we would have a perfect right to retain them until all danger from contact with others is passed.

Dr. G. H. LYMAN: I should like to ask whether under the law the board of health must isolate all persons in any one special place; cannot the board isolate them in the City Hospital as well as anywhere else? What is the difference? Does the law state that a small-pox hospital shall be for and under the control of the board of health, or that the board of health shall have authority to isolate these cases. Suppose they choose to isolate them in a tent?

Dr. DURGIN: In that event we should do precisely as we do in a dwelling house. We place our own officers there. They are our agents and have the right. We cannot make Dr. Rowe an agent of the board of health. We could go there personally if we had the right to retain a patient as in a dwelling house or in a tent. I give an unprofessional opinion in the matter. It is purely a legal question, which I don't wish to stand in the light of a lawyer in answering.

Dr. H. OSGOOD: When a patient leaves the hospital after having been confined a few days, it seems logical to suppose he is in a worse condition than when he enters, and consequently the patient is less protected than when first sent to the hospital, as we will suppose, by the board of health. I would like to ask Dr. Durgin if this society as a body could not present a memorial to any authority, either to the city or the State legislature, which will give the board of health the necessary power, and, if such a memorial would be of use, to what authority should it be presented?

Dr. FOWLER suggested that the work of the committee should be directed particularly to the investigating, and to conferring with regard to diphtheria, and not take in the other contagious diseases.

Dr. MARION: I have been extremely interested in the papers and the discussion which has been elicited, and I feel quite unequal to saying anything of importance upon the subject, feeling as I do, that the more I see of diphtheria the less positive I am in my opinions as to its nature and everything concerning it; so uncertain am I of late, that when I see a case, with reference to diagnosis, I very often say I don't know. What seems to be a case of sore throat may be a case of diphtheria. When asked how long it will last, I tell them frankly I don't know. If the child is not better within a week I think it is very serious. In ward 25, with a population of between nine and ten thousand, during October, November, and December, there were reported to the board of health seventy-four cases, I think, a very large proportion of diphtheria it seems to me; and this has been equally distributed about the ward, not being confined to any particular locality, not confined to streets where they have sewers, to houses where they have water-closets or privies wholly, where they have used well water or water from the mains. No one marked feature has been noticed except that it has been generally distributed through the ward. With the epidemic or endemic in Brighton, there has been a large number of cases of measles running along with it in the same family. The matter of heart failure has been referred to. It seems to me I have noticed that phenomenon more in this epidemic than ever before. With reference to heart failure in one family not reported as diphtheria, the child, as the mother told me, was choking. Upon examination, it seems the child had faucial paralysis with enlarged glands. All the children had had sore throats, this child included. Within a week after I first saw the child I was called again, and found three of the children down with measles. This child was with the rest, came on with the same symptoms, but instead of having a good square eruption it was very pale, the pulse hardly perceptible. The child died that night in the first stage of measles. I returned it as a death of heart failure in the initial stage of measles, heart failure from paralysis due to diphtheria. In two or three other cases of measles I have noticed heart failure.

Dr. Durgin refers to the repeated attacks of diphtheria in the same individual. In this epidemic I had a rather interesting case where a child came down with diphtheria, went through the regular stage of about ten days and recovered, and a day or two following showed the first signs of measles. The measles went through its regular course, and before the child was allowed to leave the room again a membrane developed on the fauces, and I believe it also extended into the larynx, as the child entirely lost the voice and was hoarse several days, but recovered. On the repetition of diphtheria in the child, the mother also came down with diphtheria.

Another subject that Dr. Durgin has alluded to is with reference to croup. I suppose that that is, and always will be, a disputed point. I don't know that all croup is not all diphtheria; there are some cases that certainly don't get reported as diphtheria. A case that has recently happened in the ward might illustrate what I mean. The children were all sick with measles under the care of a physician practising sectarian medicine. This child after going through the measles was attacked with croup. The child had the operation of intubation and died within twenty-four hours; was allowed to have a public funeral, was embalmed and had a "wake." Two days after the funeral the remaining two children of the family were sent to the City Hospital by my brother. On the following day I sent the woman to take care of a child during intubation, and subsequent to that there were several cases of diphtheria, but still the first case was claimed to be a case of simple pure croup. I fancy that often-times it goes that way. In connection with diphtheria it was my fortune to see several cases of diphtheria following croup; in most of these instances there was laryngeal complication, even when not coming to a fatal issue. I have an interesting case to allude to in connection with diphtheria in the puerperal state. On the 30th of November, a lady called at my office with a very severe sore throat. Being unable to

make a diagnosis I gave her directions to go home and let me know if she saw anything in the throat that looked peculiar. The next night they found a very slight patch. I at once instituted the treatment for diphtheria; and the following day the fauces, soft palate, and both tonsils were covered with the characteristic exudation of diphtheria. She expected to be confined on the 5th of December. The diphtheritic process went on its regular way, and she was confined on the morning of December 5th, Everything went well. She had a very slight elevation of temperature that day; it fell back where it had been before. It did not begin excessively high—101° or 102°, and in ten days she was convalescent, and within two weeks the fauces, I think, all cleared. The child was taken immediately from the room and in another part of the house. The child was covered with an eruption of sudamina which changed to a milky appearance and disappeared. The mother did well. When the boy was twenty-four days old I was called to see it, as it could not breathe through its nose. I found a characteristic discharge of thin yellow serum, and felt sure it was going to be a case of nasal diphtheria. The following day a whitish membrane had formed near the anterior opening in both nares, and three or four days after that a patch of diphtheritic membrane had formed in the roof of the baby's mouth, and extended back with just a trace on one tonsil. Further than that it did not extend, and it is still under treatment. The exudation has not disappeared from the roof of the mouth as yet. It is a complication, and when it was first presented I did not know what to think or how to act. It was one of the unusual complications.

Dr. McCollom, in answer to Dr. Withington's question in regard to the prevalence in the different localities of the city, presented a list of the number of cases in Boston for 1888, with the wards and relative area and the number of inhabitants. In Ward 1, fifty-nine cases. That is East Boston, comprising the hill and a portion adjoining Chelsea. Population, 15,656.

	Ward 1	59	15,656		Ward 14	41	22,738
	,, 2	16	15,700		,, 15	49	16,219
	,, 3	16	12,328		,, 16	65	16,435
	,, 4	28	12,518		,, 17	35	14,747
	,, 5	26	12,827		,, 18	27	14,141
(2)	,, 6	119	17,244	(5)	,, 19	81	20,577
(6)	,, 7	67	12,038	(4)	,, 20	85	27,983
	,, 8	30	11,286		,, 21	40	15,620
	,, 9	11	11,289		,, 22	49	15,834
	,, 10	11	9,745		,, 23	38	17,424
	,, 11	32	17,865	(3)	,, 24	110	21,500
	,, 12	31	13,845	(1)	,, 25	141	8,523
	,, 13	35	22,547				
		1,411 cases.	390,597—415,000.				

In Dr. Marion's ward (twenty-five) 141 cases. Population 8,523. This is a rather remarkable circumstance, because we would naturally suppose that to be the healthiest portion of Boston. A very great number of the houses are isolated, more so in Ward 25 than in any other portion of the city, and yet with a population of 8,524 they have had 141 cases. In all there have been reported 1,411 cases throughout the whole city during the year, and the relative frequency is, first ward, twenty-five; second ward, six; third ward, twenty-four; fourth ward, twenty; fifth ward, nineteen. There is very little to be learned from the other figures, because they are so nearly alike.

A good deal has been said about isolating these cases. Of course it is of importance to isolate them, but how can it be done? We have an entirely different state of affairs in diphtheria from that which exists in small-pox. In the first place we must educate the people up to the idea that diphtheria is *contagious*, and no one more fully realises the importance or necessity of that than I do. I hear the remarks every day that diphtheria is not contagious. "If the child had small-pox or scarlet fever we would send the child to the hospital." In some cases where the parents consent to have the child go to the hospital, the family physician comes in and says: "Oh no, you had better not send her to the hospital. The child will be better in a day or two." He can't go against the family physician. No health officers, no one, can remove a patient from any house to a hospital unless the attending physician says that the patient can be removed without injury, We cannot state that there is absolutely and positively no danger. I think very few gentlemen here would care to take a posse of police officers and remove the child from its mother to the hospital, or force the mother to go. It has been done frequently in small-pox, but the community would not sustain the Board of Health in so doing in cases of diphtheria. It can be done by educating the people up to that point; and through the influence of the members of this Society we can accomplish a good deal.

Take the cases in Brighton. Dr. Marion has sent many cases to the hospitals and done much good. Suppose some one else had been there who did not believe diphtheria was contagious, we might have had ten times as many cases in Brighton as there have been.

Another thing, a good many of these cases are not reported until after the patient's death. It is a common thing for a patient to die, and the first report we get of the case is the death certificate. The patient may have had a physician and the physician told them that the child had "sore throat," which is not reported.

It is desirable to have some place where we can send the children who are well, so that they may be watched, and the moment they come down with the disease be sent to the hospital.

As to the question of diagnosis: it is difficult in the first twenty-four hours to say absolutely, "It is diphtheria." We can advise cases to go to the hospital, but when making a forcible removal we must be *sure*. Mild cases are very apt to give rise to trouble, and the same thing is true of all contagious diseases, that the mild cases are very much more dangerous to the public health than the severe cases, because they go round everywhere and spread the disease almost indefinitely. These are some of the difficulties with which we have to contend, and for that reason I have spoken at length about them, because it is important that we take hold of the matter understandingly and see if there is not some way we can stamp out the epidemic to a certain extent.

I have seen quite a number of cases where people have had undoubted attacks of diphtheria a second and even a third time. I have in mind a case where an epidemic went through a whole family; three died and two lived; and since then there has been two attacks of unmistakable diphtheria. So far as hear-say evidence is concerned, we are constantly running across such cases. If a patient can have diphtheria three or four times we must be on our guard more than if they had the disease once in a lifetime.

Dr. H. E. Marion presented the specimen of a cast of trachea which he took from a child in 1871, thinking it a case of croup.

Dr. Farlow: As an additional means of preventing the spread of diphtheria it seems to me there is something we can do toward the well children of the family. Diphtheria is a disease much more common in children than in adults. Children are subject to nasal catarrh, etc., consequently they are much more liable to the absorption of germs; so that if there is a contagious disease in the family, I think it is incumbent on the family physician to institute preventive measures, to see if there is any catarrh about the gums, or tonsils in particular, and if so, some alkaline douche should be used. Where there is a suspicion of diphtheria I think the children should be rigorously inspected. I don't think a physician does his duty who comes into a house, gives a doubtful diagnosis, and says: "Wait two or three days," without instituting some preventive means with regard to the other children; and it seems to me that the prevention is much more important than the cure, although of course the cure is the thing the family look for. If we can prevent the disease by keeping the throat in a healthy condition we are doing very much more than most physicians are doing now. It is what we should endeavour to accomplish.

THE MEDICAL SICKNESS, ANNUITY, AND LIFE ASSURANCE SOCIETY.

An important and interesting meeting of the Medical Sickness, Annuity, and Life Assurance Society was held on Wednesday, April 17, at 38, Wimpole-street, under the presidency of Mr. Ernest Hart. There were present Mr. J. Brindley James, Dr. Major Greenwood, jun., Dr. R. Lord, Dr. F. S. Palmer (of East Sheen), Mr. W. J. Stephens (of Brighton), Dr. J. W. Hunt, and Mr. F. Wallace. Mr. S. W. Sibley, Dr. W. Bruce (Dingwall), Dr. W. M. Ord, and Dr. F. De Havilland Hall, were prevented from being present by their engagements. From the quarterly report read to the meeting, it appeared that the progress of the Society had been fully maintained, and its operations had been of a valuable and satisfactory character. The sickness experienced and compensated, though well within the rate anticipated in the tables, had been considerable—as many as sixteen claimants having been paid in one week, and over sixty guineas a week paid for two or three in succession. The illnesses included some of a very serious nature, as locomotor ataxy, chronic myelitis, iritis, and gangrene of the lung; and others of a minor character, as measles and whooping-cough. There had as well been payments on account of several cases of disablement arising from accidents. During the quarter, forty-one new members had joined, and the effective membership had risen above 950. The annual premium income was stated to be over £10,000 a year, that to the sickness fund alone being over 100 guineas per week, while the entire working expenses of the Society were under £500 a year. The total funds of the Society on March 30th amounted to £30,638, an increase of £1,919 in three months, and of £8,035 in twelve months. Of this sum £30,263 is invested on behalf of the members in the names of the four trustees—Sir T. Spencer Wells, Bart., Mr. Ernest Hart, Dr. W. M. Ord, and Mr. J. R. Upton.

The first quinquennial valuation of the affairs of the Society was produced. This has been made by Mr. F. G. P. Neison, the eminent actuary. The results are very satisfactory, the sickness rate having been found to be but 67 per cent. of the expectation, and the mortality even more favourable. A large financial surplus is the gratifying result, and though the actuary is naturally anxious to guard against premature allocation of the surplus, he speaks in high terms of the efficiency with which the Society's affairs have been conducted, and warmly congratulates the members on the pronounced success it has achieved. Information as to the Society, with printed particulars, proposal forms, etc., will be supplied free of cost on application to the Secretary, Mr. C. J. Radley, 26, Wynne-road, Brixton, London, S.W.

Medical Miscellanea.

THE subject of our next illustration will be Dr. Martin de Bartolomé.

The Matriculation Examination of the University of London will this year, and in future, be held a week earlier than before, commencing on June 1st.

* * * *

At a special meeting of the Fellows of the Royal College of Physicians, held on April 15th, Sir Andrew Clarke was unanimously re-elected president for the ensuing year.

* * * *

Mr. William Agnew has given £1,000 to endow a cot at the Children's Hospital, Manchester. He has also allowed a further extension of time of his offer of £200 towards £1,000 to be raised for the purpose of sending convalescent children to the sea-side.

* * * *

Mr. Cadge, of Norwich, has placed in the hands of the hospital authorities £10,000 towards the hospital. The *Norwich Eastern Daily Express* has the following paragraph relating to the gift: "About eight years ago Mr. Cadge said he was empowered to state that under certain conditions an 'anonymous governor' had promised £10,000 to revert to the hospital after the decease of himself and his wife. Associated with this offer was a condition that a sum of money should be subscribed by the public, and that the new building should go on to its completion. Every condition was fulfilled, but the anonymous donor continued to live on, and the £10,000 did not come into the exchequer of the institution. On Saturday it transpired that Mr. Cadge was himself the person referred to, and he will at once place £10,000 in the hands of the hospital authorities. Canon Copeman expressing the obligations of the public towards the donor of this munificent gift, said were it not for the offer of the anonymous governor the hospital would now have been without £5,000 subscribed by the public, and £2,000 by Lord Leicester, so that the institution was really indebted to Mr. Cadge for £17,000.

* * * *

Mr. William Thompson, surgeon to the Richmond Hospital, Dublin, has been appointed by the Lord Lieutenant of Ireland to the vacant seat on the Board of Governors of the House of the Industry Hospitals, from which Dr. Mapother recently retired. The selection is important, because it strengthens the influence of the medical staff of the hospitals on the Board. Since the retirement of Sir W. Stokes from the Richmond Hospital and his migration to the Meath, the Surgical side of the House of Industry Hospitals has had no representation on the Board, although Sir William still holds the seat thereon. It would be an unfortunate condition of affairs if the most important division of the hospitals remained without a delegate on the management. Mr. Thomson has also been elected at the head of the poll to be a senator of the Royal University of Ireland, a position which he has held for several years with great advantage to the interest of the medical graduates and students. Mr. Thompson's competitors were Professor Sinclair, of Belfast, and Mr. Farrelly, who represented the radical element of the Convocation at one time, but lost his seat a year ago. The voting was:—Thompson, 522; Sinclair, 493; Farrelly, 93.

CHILDREN'S HOSPITAL, LEICESTER.—With the object of adding to the funds necessary to the establishment of a Children's Hospital, a very successful concert was given in the Floral Hall, Leicester, on Monday Evening, April 8th, by the Reed Band connected with the works of Messrs. John Richardson & Co., Friar Lane. The concert was well patronised by all sections of the community, the hall being crowded in all parts, which fact tends to prove the popularity of the movement. The performances of the band (which comprises thirty instrumentalists, all employees of the firm) were excellent and a most gratifying reception was accorded to them. The following was the programme:—Overture, "Titus" (*Mozart*); polonaise by the Prince of Oldenburg; selection, "Faust" (*Gounod*); cornet solo, "The Lost Chord" (*Sullivan*)—solo by Mr. H. A. Allingham; waltz, "Brise des Nuits" (*Lamothe*); selection, "The Yeomen of the Guard" (*Sullivan*); fantasia, "Concord" (*Buot*); selection, "Dorothy" (*Cellier*); clarinet solo from "Ernani" and "Sonnambula"; (solo by Mr. H. Burbidge); fantasia, "Reminiscences of Wales" (*F. Godfrey*); galop, "Post Horn" (*Kœnig*). Previous to the concert the members of the band presented the conductor (Mr. H. N. B. Richardson) with a handsome silver-mounted baton, bearing the inscription—H. N. B. R., from his band, 8th April, 1889. After all expenses were paid the handsome balance of £25 was handed to Ald. Wright, chairman of Children's Hospital Fund.

The annual dinner of the Pharmaceutical Society of Great Britain will take place at the Freemasons' Tavern on Tuesday, May 14th, at 6-30 for 7 p.m.

* * * *

A handsome brass, mounted on marble, and dedicated to the memory of the late Professor du Chaumont, M.D., F.R.S., has just been placed (with the sanction of the War Department) in the chapel of the Royal Victoria Hospital at Netley. The subscribers to the memorial were limited to the past and present members of the teaching staff of the Army Medical School.

* * * *

The organisation of the Continental Anglo-American Medical Society has proceeded so far, that it has been arranged that the first general meeting shall be held on September 30th. Sir Spencer Wells, Sir Joseph Lister, Dr. Quain, Professors Ball and Brown-Sequard, have been asked to become honorary presidents of the society. The executive committee consists of the following gentlemen, resident in Paris: Dr. the Hon. Alan Herbert, Dr. Faure-Miller, Dr. Chapman, Dr. E. Dupuy, Dr. Barnard. The secretary is Dr. Thomas Finn, 16, Rue de la Paix, Paris.

* * * *

At the ordinary meeting of the Wigan Medical Society, held in the board room of the Royal Albert Edward Infirmary, Wigan, on Thursday the 11th inst. Mr. Hardie, F.R.C.S., Eng., Surgeon to the Manchester Royal Infirmary, gave an able and instructive lecture on Plastic Surgery illustrated by numerous photographs. There was a good attendance of members, and the lecture was highly appreciated. At the same meeting the following resolution was submitted by the president and carried *nem. con.*:—"That this Society cordially approves of the bill about to be presented to Parliament by which it is proposed to restore to the members of the College of Surgeons a free and unrestricted exercise of their ancient rights and privileges."

* * * *

During the Exhibition at Paris there will be a number of medical congresses. The International Congress of Therapeutics and Materia Medica will be held at Paris on the 5th of August, 1889, at 28, Rue Serpente, in connection with the Universal Exhibition. Medical men, apothecaries, and veterinary surgeons who shall have sent in their names and paid the fee of ten francs will be entitled to take part in the proceedings. The committee is composed as follows:—President, Dr. Moutard-Martin; Vice-President, Dr. Dujardin-Beaumetz; Secretaries, Drs. Constantin Paul, P. G. Bardet, Labbé, and R. Blondel. The Congress will be divided into two sections—Therapeutics, and Materia Medica—and the discussions will be carried on in different halls. The following subjects will be discussed: Antipyretics and Analgesics; The Antiseptics suitable for each Species of Pathogenetic Microbe; Cardiac Tonics, their Nature, etc.; New Drugs of Vegetable Origin recently introduced into Therapeutics; The Unification of Weights and Measures in Prescriptions, and The Advantages of an International Pharmacopœia. Members of the profession wishing to attend the Congress should communicate with Dr. Bardet, 119*bis* Rue Notre-Dame-des-Champs, Paris. The titles of papers proposed to be read before the Congress should be forwarded to the secretary before May 15th.

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the EDITOR, "*The Provincial Medical Journal*," *Horton House, Halifax.*

Matters of business should be addressed to the Publisher, at the Offices, 10, *Friar Lane, Leicester.*

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked.

Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16th of the month.

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

AMENDMENTS TO FRIENDLY SOCIETIES ACT 1875.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—The following is a list of amendments to the Friendly Societies Act of 1875, which shall be posted this day to the House of Commons Committee on Friendly Societies now sitting:

(1.) It shall be an offence for any president, secretary, or committee-man to receive a bribe from the medical staff, chemist, or dispenser, or from members or parties receiving death-claims, or allowances for sickness; or not to surrender to the society's funds reductions made for commodities or services for the society secured or employed. No society within the meaning of the Act to be exempt from this subsection.

(2.) It shall be an offence for any president, chairman, or committee of a friendly society included in the Act, collecting more than three miles away from the place of meeting, to expel any officer not guilty of theft or of embezzlement, or any member not out of benefit, from the society; or to exclude from a general meeting any officer or member. Such actions shall be deemed infringements on the rights and prerogatives of the members at general meetings.

(3.) It shall be an offence for any president, chairman, other officer or officers, to close a general or other meeting without a vote to this effect from the members present. No society included in the Act shall be exempt from this injunction.

(4.) While a general meeting may pass a resolution for calling a *special* meeting of the members, it shall be deemed a misdemeanour for any president, or other officer or officers, or the committee, or any party aggrieved, to exercise this power only through the medium of the Chief Registrar with the consent of the Treasury. This subsection shall extend to every society within the provisions of the Act.

(5.) It shall be an offence for any president, other officer, or for the committee to practically ignore or disobey an injunction, order, or decision, of a general meeting of the society. This subsection shall include every society within the meaning of the Act.

(6.) It shall be an offence for any collector, or for an inspector of collectors books or cards, to vote, take part in, or to be present at a general meeting; and an offence for any president, chairman, or committee-man to tolerate at a general meeting the presence of a collector or an inspector. This subsection shall include every society within the provisions of the Act.

(7.) While general meetings of members or of delegates shall have full power, in accordance with dictates of justice, to modify, augment, or diminish the salary of any officer or servant, it shall be deemed a misdemeanour for any officer or officers to assume this prerogative. No society, included in the Act, shall be exempt from this subsection.

(8.) That parents and guardians entering and paying subscriptions for young persons, shall in all societies within the provisions of the Act, have power to vote and take part in general meetings, and it shall be an offence to prevent their doing so, rules to the contrary notwithstanding.

(9.) That as the health and lives of the members generally are entrusted to the medical staff, and as it is an imperative necessity that a medical officer should be estimated according to his merits, and not by his submitting to bribery, no president or other officer, or committee, shall be empowered to employ, discharge, or suspend, or to alter the salary or fees of a medical officer. All matters relating to the conduct, and all jurisdiction over the medical staff, shall be exercised solely by the members at general meetings. No society employing medical assistance, included in the Act, shall be exempt from this subsection, and violations of which shall be deemed offences.

(10.) That it shall be an offence, involving the president, secretary, and the committee, not to send yearly medical and other accounts to the Chief Registrar, or not to supply the members with a correct statement of the said accounts annually. This subsection to apply to all societies under the provisions of the Act.

PHILALETHES.

THE MEDICAL ASPECTS OF BOURNEMOUTH AND DR. CRESPI'S ARTICLE ON BOURNEMOUTH AS A HEALTH RESORT.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—My attention has been called to-day (April 13) to the following editorial remarks in *The Bournemouth Guardian* :—"In a long article, in the April number of the PROVINCIAL MEDICAL JOURNAL, on Bournemouth as a health resort, from the pen of Dr. A. J. H. Crespi, of Wimborne. . . . the writer attacks Dr. Dobell's work on the 'Medical Aspects of Bournemouth,' and complains that Bournemouth is not what Dr. Dobell makes it out to be. 'Dr. Dobell,' he says, '*does not hesitate to claim for Bournemouth the proud pre-eminence of having the most perfect and genial climate under the sun*, and fewer people would leave it disappointed were the descriptions, that are published, more in accordance with fact; but when people are told that they will find a perfect climate, and that the sun always shines there, even on the coldest day, they cannot fail to be disappointed."

"We have seen Dr. Dobell's work, but we do not remember having read in it a statement that Bournemouth enjoyed an endless day of cloudless sky and bright sunshine. . . However, we leave the contradiction of this statement to Dr. Dobell himself, together with the inference which Dr. Crespi makes from the comparative barometrical analysis with which he furnishes his readers."

Since reading the above, I have looked through Dr. Crespi's article, which had hitherto escaped my notice; and as I have no reason to suppose that he wished deliberately to misrepresent what I have written, I can only conclude that he followed a common rule with literary critics—viz., "Not to read a book till after you have made up your mind what you mean to say about it;" otherwise, he could not have described my book as "A Guide Book." He says, "*Guide Books* to the place, of course, abound, the most complete, perhaps, is 'The Medical Aspect of Bournemouth,' by Dr. Horace Dobell;" nor could he have complained that it "goes too much into medical details, and is somewhat disfigured by reports of over forty cases;" nor could he, in common fairness, have quoted the meterological tables as mine, and suppressed the clear statement made by me that they were Dr. Compton's, and not mine; nor could he have penned the extraordinary statement which I have copied from *The Guardian* newspaper.

The following extracts from my book will substantiate the foregoing observations :—"The fashionable way of writing a book about a health resort has long been to enter it in a competition with a number of other health resorts, in an elaborate and perplexing comparison of skilfully manipulated tables of temperature, rain-fall, barometric and hygrometric readings, sunshine, wind, mortality, etc., in which by some miraculous, mysterious, or 'fortuitous conflux of atoms,' the place in question always manages to turn up trumps upon the vital points. Sympathising alike with the famous words of Lord Beaconsfield, 'Confound your figures,' and with the old axiom that 'Comparisons are odious,' I have decided to *avoid* both the comparisons and the figures, so far as I possibly can, and to adopt a method of placing my opinions before my readers, which I hope may be as much more congenial to their tastes, as it certainly is to mine. Again, it has been usual in medical books about health resorts, to make them also local '*Guide Books*.' I intend, in this work, *to avoid*, as far as I can, *all but the medical aspects* of my subject. Fortunately, all the necessities of a 'Guide Book,' have been well supplied already in 'Hankinson's Descriptive Guide to Bournemouth, Christchurch, Wimborne, etc.' . . The way is thus cleared for me to proceed at once to treat of the *purely medical* aspects of my subject. In the first place, I must remark that neither Bournemouth, nor any other part of the United Kingdom, has a climate exactly like that of Africa, Australia, Egypt, the Andes, Minnesota, Iceland, Davos, the Rocky Mountains, or the Nubian Desert, either in summer or winter! From the expectations with which I have found the minds of some patients filled, when sent to Bournemouth, the above apparently trite remark is not so altogether unnecessary as it might at first appear to be."

With regard to the meteorological tables, which it must be observed are not once referred to in the body of my work, and are only placed in an appendix, I headed them with the following statement :—Dr. T. A. Compton, M.D., B.A., Fellow of the Royal Meteorological Society, has kindly submitted to me his accurate and elaborate records taken in the Bournemouth district during the eighteen years 1867 to 1884 inclusive. The results have never before been published, and *notwithstanding my desire* (stated in chapter 1) *to avoid figures*, as far as possible, I feel it would be wanting in respect for Dr. Compton's courtesy in placing the records before me, and for the great labour which he has bestowed in reducing them to a concise and presentable form, if I did not at least publish the following summary of some of the chief points contained in his reports, which more especially relate to the general statements contained in this book." How far Dr. Crespi's version of what I have said in my book about climate corresponds with the facts will be best shown by giving the following extract, in which I summarised all that I had written on the climate of Bournemouth. This summary has been accepted as accurate by those who know Bournemouth best, and it has been quoted in various places, among others in the *Holiday Number of the London Medical Record* (1887), in which the editor added, "a great variety of other medical opinions might be cited, but after Dr. Dobell's carefully considered words, this must surely be unnecessary."

"It is the combination of (*a*) moisture-laden sea-breezes coming in from the south; (*b*) diluted and partially dried as they are by condensation of moisture on the face of the cliffs, and by admixture with the upper, drier, and less saline atmospheric strata, as they rise to the tops of the cliffs; (*c*) the important chemical changes which take place when the watery vapour mixes with the terebinthenate emanations from the pines; (*d*) the immediate absorption of all relundant moisture by the soil; (*e*) the dryness of the soil with the rapid percolation of the absorbed moisure to a great depth from the surface, and the numerous subterranean conduits by which it finds its way to the sea; (*f*) abundance of sunshine from the wide expanse of sky, and the catching of clouds by rain-traps; (*g*) free circulation of fresh air in consequence of the houses being built upon an elevated plateau instead of under the cliffs or upon sea-level flats, and of the heathland character of the surrounding country; and (*h*) the protection afforded by the pine-woods—which give the climate of Bournemouth at once its softness, its freshness, its purity, and its antiseptic properties—a combination peculiarly difficult to obtain."

"It is not easy to conceive any other combination of conditions by which to obtain (*a*) *anti*septic properties without the objection of over dryness of other irritating qualities; (*b*) *a*septic properties without the objection of excessive cold; (*c*) a marine air without the objection of overcharge with saline ingredients; (*d*) a soft air without the objection of excessive moisture; (*e*) coast air without the objection of malaria, and without undue exposure to storms; (*f*) shelter without the objection of deficient atmospheric circulation; and (*g*) last, but not least, a combination of the brightness and grandeur of the sea, with the varied loveliness of the surrounding pine and rhododendron woods, heaths, lanes, and glades; and further afield—but still within an invalid's drive—the picturesque and soothing river scenery of the gravelly-bottomed, rapidly-flowing Avon and Stour, with their salmon fisheries; the wide-spread rural landscapes towards Canford and Wimborne; and the wonderful views of distant sea and sky from the moorlands and fir woods of Constitution Hill.—(pp. 34-35, second edition, 1886)."

It is quite clear that Dr. Crespi does not frequent the Churches at Bournemouth, or he could not have said "the churches seem far in excess of the requirements of the scanty population," the fact being that Sunday after Sunday, both in winter and summer, it is painful to see the visitors hurrying about from church to church, trying to find seats, and often at last obliged to go home without finding them.

I am entirely in accord with Dr. Crespi in his complaint that Bournemouth invalids and visitors want more amusements in bad weather; and if he reads the local papers, he must know that I have been "agitating" for some years to obtain a large "Central Rendezvous," between the pier and the pleasure gardens. My designs and the architect's drawings and plans are in the hands of the Commissioners, and I am informed that they will be carried out as soon as a charter of incorporation has been granted to the town.

Dr. Crespi calls the population "scanty," and sets it as from 20,000 to 25,000; whereas the latest and most careful computation (see Dr. Kinsey-Morgan's new book on "Bournemouth as a Health Resort") makes it 32,000; and he speaks of there being "sixty medical men in *active* practice," which is sheer nonsense! There is a host of invalided and retired doctors in the place, but there are not twenty-five doctors "in active practice" at the present time; and as I intend to retire before the end of the year, there will be a gap which no one in Bournemouth seems exactly qualified to fill. It must be remembered that in a health resort of this class, the number of invalids to population is out of all proportion to that in ordinary places.

In conclusion, I must state that *I was not* the "leading Bournemouth doctor," who, Dr. Crespi says, sat in the same carriage with him last year, and who he accuses of having knowingly told a deliberate falsehood about the climate of Bournemouth to an innocent "great Metropolitan luminary." Who that "leading Bournemouth doctor" was I do not know, so I must leave it to him to deal with Dr. Crespi's "charitable speeches" if he thinks it worth his while.

Yours truly,

HORACE DOBELL, M.D.

REPLY TO DR. DOBELL.

To the Editor of The Provincial Medical Journal.

Dear Sir,—A newspaper correspondence is the most unsatisfactory thing in the world, and never does one particle of good, and so while in replying to Dr. Horace Dobell's strictures on my Bournemouth paper, I depart from a long-standing rule of mine. I do not expect that he or I will be gainers, but will be the rather confirmed in our respective opinions.

No one can read that article carefully without seeing that I have attempted to be perfectly fair, and to touch upon every point of interest. While I speak most warmly of the climate and the place, I do, however, complain that the former is often misrepresented, and I find fault with Dr. Dobell, in all courtesy though. His work contains a vast amount of information, deeply interesting, often curious, almost always useful and accurate; but I take exception to it on two grounds: I complain of the medical details of cases so freely introduced, and which give the work in places an appearance of advertising, which Dr. Dobell could not but object to himself in any similar work treating of another health resort, and the climate is described in language that I consider exaggerated. Were the book placed in the hands of any Scotch or North Country practitioner, especially of one ignorant of meteorology, he would fancy that Bournemouth had a perfect climate. Page after page will bear this construction, and Bournemouth is represented as having a combination of climatic advantages not found in any other place named. Dr. Dobell gives whole chapters describing the drawbacks of the climate of Italy, of foreign travel, and much more, which certainly justify my strong remarks. On page 220 occurs the passage, "it was during the *one week* of very bad weather." That sentence conveys volumes. Only think of a place in our latitude that has but one very bad week in the whole year.

Dr. Dobell seems offended at my calling his the most complete guide book to Bournemouth. In spite of his disclaimer I shall continue to look upon it as such. It cannot, in spite of its title, be regarded as a strictly medical work, and it is bought and read by many people, who are not doctors, under the impression that it is a complete guide to the place.

Some parts of Dr. Horace Dobell's letter I cannot quite follow. He has some fault to find with me for not stating that the Meteorological Tables are drawn up by Dr. Compton. I do not deny their accuracy, and no one else does; have I said that Dr. Dobell drew them up?

I repeat that many people come to Bournemouth expecting to find a climate far warmer, calmer, and brighter than it really has. Much of this disappointment is to be traced to highly coloured accounts of the place and climate, accounts which a meteorologist would smile at, but which the public accept as true. I have known people come from Bath, Cardiff, Birmingham, and Berkshire, expecting to find the warmth of a Midland June at Bournemouth in November and December, and complaining bitterly when they found that they had been deceived.

Dr. Dobell accuses me of not having read his book. Let me turn the tables upon him. He is anxious that he should not be confounded with the "leading Bournemouth" practitioner whom I met last year; but earlier in my article I distinctly say that I have never seen Dr. Dobell.

To one or two other points I must refer, though they are of secondary importance; they, however, reflect gravely on my accuracy. He treats the statement that there are sixty-one practitioners as "sheer nonsense," and adds that there are "not twenty-five in actual practice." The current issue of the "Medical Directory" gives sixty-two names, one only being marked "retired," and there are five at Parkstone; in addition to these the Poole and Christchurch men live on the outskirts, and sometimes are in the place; and there are one or two other practitioners as near, who are correctly given under the heading of their own villages. He also complains that the population is 32,000, not 20,000 to 25,000. Now on both points. Three years ago the late Mr. Gamgee, of Birmingham, was again thinking of settling at Bournemouth, and asked me to make inquiries for him. I will not give names, for all the letters went in to Mr. Gamgee, but a surgeon of mark told me he knew forty-one doctors in practice, and the number was increasing fast; he laughed at the number of retired and invalided men being large. Other men said and wrote the same. As for the population, they represented that the figures generally given included Christchurch, Poole, and Parkstone. If Dr. Dobell will refer to the "Medical Directory" of this year he will find that the population of the Urban Sanitary District is given as 16,858. I thought that in adding from 4,000 to 8,000 I was being generous.

I have too high an opinion of Dr. Dobell's merits and ability to write an unkind word about him, but I fancy he will agree with me that Bournemouth is a truly wonderful place in more ways than one, not the least wonderful being that in addition to some *retired* men whose names do not appear in the "Directory," there are nearly fifty whose names do figure in it.

The "Medical Aspects of Bournemouth" is so well got up, and valuable, that I strongly advise my readers to get copies. They will enjoy reading it, and I am sure that while they will not like Dr. Dobell the less, they will agree that in my passing criticisms I have not been too hard on him, and have not misrepresented any passages of his book.

I remain, your truly,

Wimborne. ALFRED J. H. CRESPI.

PASTEURIAN STATISTICS.

To the Editor of The Provincial Medical Journal.

Sir,—At the inauguration of the Pasteur Institute, M. Grancher is represented to have said that the English Commission in the early part of 1887, after long and careful investigation for itself, came to the conclusion that "M. Pasteur had discovered a preventive method for hydrophobia, comparable to that of vaccination against small-pox." This is true, but that decision does not cover the claim heretofore made by M. Pasteur in reference to his cases in human beings. The decision of the Commission was said to have been arrived at by means of experiments conducted on the lower animals, but, as I have so frequently pointed out, no attempt was made to test by experiment the value of the treatment *after infection* had taken place.

I must confess that, the formidable array of figures, manipulated, as they are, with such apparent ingenuousness, would be overwhelmingly convincing if—and here this little word assumes its biggest proportions—they were founded on undoubted facts. It has been frequently explained that it is impossible to tell save in those cases when the symptoms of hydrophobia have supervened whether a person has been *inoculated* with virus or not. In this connection we find in an article in the *Field*, January 4th, 1889, a new and marvellous admission, which virtually concedes everything M. Pasteur's opponents can desire. We are now for the first time told that, when death occurs either during the treatment or within a fortnight of the completion of the inoculations, such deaths must be eliminated from the mortality table, because the patients—to quote the words of the writer—"must already have had the poison in their systems before they came under M. Pasteur's treatment." This is about the most audacious of all the audacious shifts which have been made from time to time in the face of adverse circumstances, by M. Pasteur or his partisans. It is too, nothing less than an insult to our understanding to ask us now to judge of the value of Pasteur's statistics by the aid of such an absurd process of elimination, especially so, when we recollect the absolute claim to success that has been, and still is being, advanced for the method at whatever period adopted before the advent of symptoms of hydrophobia. Further, if unfavourable data are to be thus eliminated because they prove that Pasteur's treatment is useless when once infection has taken place, of what value, may I ask, are the favourable data, the only certain point in regard to which is that infection has not taken place? M. Grancher's statement amounts to this, as we have so persistently held, if Pasteurism is of any value at all that it is merely as a prophylactic, and not a remedy. If, as I suspect, it is meant that Pasteurism is of value only in those cases in which the rabic virus remains for a sufficient length of time, localised at the injured part before being taken up into the general circulation, then I may ask what same persons would hesitate in his choice between excision and Pasteurism? But if Pasteurism is successful under such circumstances, how does M. Pasteur account for the death of a man more than two years after he had been submitted to the treatment, and for the many deaths that have occurred, notwithstanding the early recourse—in many cases within a week—to the treatment! Again, what becomes of the value of those oft-quoted, numerous, successful cases, in which a fortnight, three weeks, or a month, had elapsed between the injuries by supposed rabid animals, and the commencement of the treatment.

While Pasteur has persistently ignored the challenge to prove his position by experiments on the lower animals, he invariably marshals out his brilliant array of statistical figures, and insists upou the exclusive right to manœuvre them to a "pot-pouri" of his own composing. M. Pasteur seems to forget that statistics are like an impecunious but large-hearted Irishman—anybody's friend. That Pasteur's apparent success is due almost entirely to "scare" is sufficiently evident from the fact—quoting M. Grancher's figures—that the number of cases treated at the Pasteur Institute fell from 2,682 in 1886, to 1,386 in 1887; the average mortality from hydrophobia, it is said, being only 40 per annum in the whole of France. How could the death-rate to number inoculated be anything but low under such circumstances?

It was wise of M. Pasteur to point out "that the Institute would serve not only for inoculation against hydrophobia, but that numberless other researches and experiments as to the diseases produced by microbes would be carried on there." I venture to assert that when the "scare" passes away, it will be these researches alone which will save the Institute from ruin and disgrace.

VINCENT RICHARDS.

A DIAGNOSIS WANTED.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—A man, æt. forty-two years of age, blacksmith by trade, very strong looking, weighing about fifteen stone, and somewhat corpulent, has been ailing for the last seven years from what he describes in his own words as nervous exhaustion. Before then he never ailed anything; was very thin and spare in body, but since his illness began he has got to be very stout and fat. For the first two years of his illness he had extreme pain at the lower part of the back, over the sacral region; afterwards he suffered for about eighteen months from sickness, especially in the mornings. Neither of these trouble him now. At present his feeling is one of extreme weakness, with an aching pain in front of the thigh and a trembling feeling in his legs. He has noises in his head which are like a distant thrashing machine, sometimes worse than others, but seldom absent. Often in the mornings, between sleeping and waking, he feels as if he would go out of his mind; sees things before him, and says it is like being in the "blues." He has often told his wife when these feelings come over him that he is not at all surprised at people putting an end to themselves. He is fretful and irritable and does not like to see anyone.

Physical examination does not reveal any abnormality. He suffers slightly from cough in the winter time. Urine is usually loaded with urates; once it was found decidedly albuminous; it has often been tried and only a haziness produced. He only passes about forty ounces per day; when at his work, less. He perspires profusely when doing anything; often in bed he says his legs are cold and clammy. He suffers occasionally from slight œdema of the legs.

Yours truly, JUNIOR.

PYRETIC ACTION OF ANTIPYRINE.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—In a letter to your valuable Journal on the above subject in May, 1888, I pointed out that the antipyretic power of antipyrine and similar drugs was due to their action upon the elements of fibrin—an action which either prevented their union or made the fibrin of so unstable a form that the stasis of blood in inflammatory diseases was either entirely prevented or considerably modified. Confirmatory evidence of this view being correct, I have found in the result of treatment of the commonest disease of leeches after they have drawn blood. In a longer or shorter time from contraction of ingested material they become hard and corrugated. On treating these with a solution of antipyrine of the strength of fourteen grains to the pint they in three days regained their usual size, suppleness and activity, after discharging and vomiting shreds of fibrin and a quantity of hœmoglobin; three washings or cleansings were sufficient at intervals of eighteen hours.

I am, Sir, Yours truly,

April 21st, 1889. C. R. ILLINGWORTH, M.D.

BRONCHITIS TREATED BY FELLOWS' SYRUP OF HYPOPHOSPHITES.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

DEAR SIR,—I have recently been informed, by medical friends, of some very grave cases of bronchitis successfully treated by my preparation (Fellows' syrup of Hypophosphites), and, as I feel that many members of the profession are unaware of its value in this form of disease, I venture to ask you to test its virtue, if you have not already done so, in either acute or chronic bronchitis, however hopeless the cases may appear, as I feel convinced that the result will prove satisfactory.—Apologising for thus troubling you, I am, dear Sir, yours very truly, JAMES I. FELLOWS.

April 10th, 1889.

Bibliographical Record.

BOOKS, PAMPHLETS, ETC., RECEIVED.

The Early Symptoms and the Early Treatment of Osteo-Arthritis (commonly called Rheumatoid-Arthritis), with special reference to the Bath Thermal Waters. By John Kent Spender, M.D. Lond., etc. pp. 59. London: H. K. Lewis.

The Practice of Medical Men in Switzerland. pp. 72. By Cevester Brothers. Geneva.

The Therapeutics of Kronenguelle Water. By Prosser James, M.D. pp. 32. London: Trübner & Co.

Elementary Bandaging and Surgical Dressing; with Directions concerning the Immediate Treatment of Cases of Emergency. For the use of Dressers and Nurses. By Walter Pye, F.R.C.S. Third edition. Bristol: John Wright & Co.

The Medical Annual and Practitioners' Index. 1889. pp. 600. Bristol: John Wright & Co. ☞ This publication is simply invaluable. It increases in volume and usefulness each year.

The Essentials of Physical Diagnosis of the Chest and Abdomen. pp. 156. By J. Wallace Anderson, M.D. Glasgow: James Maclehose and Sons.

Remarks on Fifty Consecutive Cases of Empyema occurring in the Wards of the General Infirmary, Leeds. By Thomas Wardrop Griffith, M.B., C.M., Professor of Anatomy in the Yorkshire College, Physician to the Leeds Public Dispensary.

The Utility of Experiments with Drugs and Animals. By Edward Berdoe, L.R.C.P. London: Swan, Sonnenchein & Co.

Bournemouth as a Health Resort (*illustrated*). By A. Kinsey-Morgan, M,R.C.S. London: Simpkin, Marshall and Co.

Man and his Maladies, or the Way to Health: a popular hand-book of physiology and domestic medicine in accord with the advance of medical science. By A. E. Bridger, B.A., M.D. London: John Hogg.

Lectures on Pathological Anatomy. By Samuel Wilks, M.D., and the late Walter Moxon, M.D. Third edition, thoroughly revised by Samuel Wilks, M.D.

Our Portrait Gallery.

MARIANO MARTIN DE BARTOLOMÉ, M.D.

THE features of Dr. Martin de Bartolomé must be familiar to all who have attended meetings of the British Medical Association. He is one of the band who in times past, when the profession was disorganised, set themselves the task of building up an association which should gather within its folds all members of the profession. The early days of the British, or as it was then called, the Provincial Medical Association, were days of struggle. Its members were but a few thousand: its journal was weak, and financially unsuccessful. The forces against it were powerful, but Dr. Martin de Bartolomé has been spared to witness the powerful growth of the organisation, and he might truly say, *jam satis vixi.*

Many of his old companions in arms have joined the majority; fortunately, a few of his old friends are spared, as Waters, Strange, Wheelhouse, to rejoice with him in the great and growing success of the British Medical Association. We have now an amended constitution more in harmony with the temper of modern times. Representation on the Council is secured to the branches by popular vote, so that each member of the association is thus able to influence the Council. We have now a journal, which each year brings in a large profit, and we have now somewhat like 13,000 members; and in the future there is every promise that it will reach 15,000 or more. The husbandman sows a tree to benefit future generations. The seed sown by Sir Charles Hastings and others has blossomed into a goodly tree, under whose shade we now sit in peace and content; but whilst enjoying it we should not forget those who have planted it. We have published short memoirs of the leaders in the establishment of the British Medical Association—as Drs. Waters, Strange, Mr. Wheelhouse, Mr. Ernest Hart, etc.—and we have pleasure in giving a short memoir of one of their most esteemed *confreres.*

Mariano Martin de Bartolomé was born in Segovia, in Spain, in 1813, of an old Castilian Hidalgo family, and in consequence of his father being "Jefe Politico," or civil Governor of the province, was entered in the celebrated Artillery College of the Alcazar of Segovia when only eight years of age, and received his early education at that national institution. The destruction of the representative system of government, and the restoration of the despotism of Ferdinand the Seventh by the French intervention, drove the family out of Spain to seek a refuge in England.

In 1833 the future doctor matriculated; and in 1838 took the degree of M.D. in the University of Edinburgh, and was one of the twenty-one optimi of that year (out of ninety-eight graduates). During the last three years of his residence at the University he was confidential assistant in the laboratory and lecture room to the late Sir Robert Christison.

In 1840 Dr. Martin de Bartolomé was elected Physician to the Sheffield Public Dispensary.

In 1846 he was elected Physician to the Sheffield General Infirmary, and also Lecturer in Medicine at the Sheffield School of Medicine, both which appointments he still holds. In the same year he obtained letters of naturalisation as a British subject.

He has been President of the Sheffield School of Medicine for twenty-two years, and in 1864 the pupils of that, and previous sessions, presented him with a handsome piece of plate in recognition of his services. In 1874 he was President of the Yorkshire Branch of the British Medical Association, and in 1876 of the Association itself.

In 1888 the medical profession of Sheffield and the neighbourhood subscribed liberally to an oil portrait of the doctor by Bernard Cammell, Esq., and with characteristic good taste presented it to the Sheffield School of Medicine—the scene of his labours—and it now hangs in the library of the new building.

Dr. Martin de Bartolomé has been married twice, and has eight children.

Original Communications.

GYNÆCOLOGICAL SPECIALISM AND GENERAL PRACTICE.[1]

By THOMAS M. DOLAN, M.D.,
VICE-PRESIDENT BRITISH GYNÆCOLOGICAL SOCIETY.

IT would be singular indeed if the medical profession escaped from the action of what I might term the general forces, which have of late years so acted upon manufactures and the arts, as to bring about in these a degree of specialism unknown, and even undreamt of, by our ancestors. It has not escaped, and my object to-night is to attempt to prove that those who are engaged in general practice have no reason to complain of the growth of gynæcological specialism, which has followed on the line of progress and of evolution, for general practitioner and specialist have still their *rôles*, and are mutually interested in the development of the study of the diseases of women; nay, more, I would assert that by linking themselves closer with such a society as the British Gynæcological, and by digesting the experiences which the leaders in gynæcological practice so readily place at their disposal, general practitioners can thereby better qualify themselves for that position which, if I read rightly the signs of the times, they are likely to hold in the future. It is nothing new when I say that the prospect of the future appears to hold out almost a certainty, that the differentiation in the ranks of the profession will be of such a nature that we shall have two orders.—First, a family physician or medical attendant, who will have the general care of the public; and, secondly, that we shall have behind them an order who devote themselves exclusively to the study of a single part or parts of the body. It is a growing opinion that the specialist should for some years be a general practitioner, and that then by predilection for some individual organ or part of the body, he should take up that as his speciality. It is doubtless true that we have a number of specialists who have not been in general practice, but they have served a similar apprenticeship in connection with general hospitals, and, *mutato nomine*, the end is similarly achieved, experience being acquired which determines the value of the specialist in our eyes.

The signs of the times appear to me to point to this, and I cannot help thinking that such a change will be conducive to the best interests of our patients, for after all, and above all, that is the chief point. The field of medicine, and especially of gynæcological medicine, is so vast that it is only permitted to the general practitioner to have sufficient knowledge to treat the ordinary diseases of womankind; at the same time he should be able to accurately diagnose those conditions, for the relief of which he should seek the aid of those who have taken up the speciality, and what those conditions are we shall subsequently see in the outline survey I shall give. The field of general practice, so far as the diseases of women are concerned, leaves to us an enormous scope of work almost sufficient to satisfy any ordinary ambition; and if we are sufficiently qualified to faithfully, judiciously, and scientifically carry out the treatment of the general ailments of women with minor surgery, we may congratulate ourselves—even though we cannot lay claim to major operative honours—that we are in some measure contributing to the advance of gynæcology, and to the happiness of that sex to which our study is devoted. The diseases of women and children have from time immemorial been associated with general practice. In fact there would be nothing worthy of the name if we took away these classes. By the practice of obstetrics we in the first place obtain a firm hold in family practice, and the subsequent attendance follows almost as a matter of course.

I shall briefly allude to some groups of symptoms about which we are commonly consulted, and submit some reflections upon them from the general practitioner's point of view. Disorders of menstruation take first place. Here in connection with this most important function we have almost the commencement of our gynæcological work—in advising and laying down, under normal conditions, the hygiene of the period. Apart, however, from normal menstruation, a large number of conditions or symptoms, as amenorrhœa, dysmenorrhœa, menorrhagia, metrorrhagia, fall under our notice, calling for the highest diagnostic faculty and experience. The general practitioner who aims at really securing the confidence of his patients should be well grounded in the causes which lead to any of these states, and here he will find that even with such a symptom as amenorrhœa he will have a wide scope for philosophising. He will have to enlarge his mental vision, not looking at it as simply demanding the exhibition of that great panacea, "iron," or the use of that implement of destruction, the sound, but as calling for a philosophical enquiry which will embrace all the elements of the gynæcological A B C—for if he in the one case gives iron for a case of amenorrhœa, depending on absence of the ovaries and uterus, he will cover himself with confusion; if he uses the sound when amenorrhœa depends on pregnancy he will be guilty of criminal abortion.

This mistake has been made not only by general practitioners, but by physicians and surgeons of repute, and here I would remind you of the words of a song which was written for the lover and not for the gynæcologist, but which are applicable to both.

I knew a maiden fair to see,
Take care, take care;
She can both false and friendly be,
Beware, beware,
She is fooling thee.

The air of innocence assumed by some patients who come to us with amenorrhœa; the social surroundings of the patient may put us off our guard, but we should ever remember the possibility of pregnancy.

The other possibilities opened out by amenorrhæa are very wide. From simple anæmia as a cause, we touch conditions which will require operation, such as when we have associated with this state, vaginal or uterine atresia, with which we may have reflux of blood into the fallopian tubes, with even rupture and escape of blood into the peritoneum. This condition is supposed to be rare, but none the less is it our duty to be mindful of these conditions and make our diagnostic range so comprehensive as never to omit a consideration of the possible. Intra-peritoneal hæmorrhage in the virgin I believe to be more common than we imagine, and to be the unsuspected cause of many deaths. The local morbid conditions associated with amenorrhœa, or causing it, such as ovarian tumours, peritonitis, parametritis, ovaritis, apart from other causes associated with anæmia, should all pass under our mental ken. Thus alone can errors of diagnosis be avoided.

[1] A paper read at the British Gynæcological Society, May 22nd, 1889.

Here I would observe in reference to the therapeutic treatment of one single symptom, associated with amenorrhœa, that I think the value of iron is over-estimated, and that the routine pill of doses of sulphate of iron has little or no value. Iron represents strength, and its routine prescription appears to me to depend very much on an association of ideas rather than on its practical efficacy. Apart from the hygiene proper to anæmic conditions I set a very much higher value on arsenic and nux vomica. Next in frequency to amenorrhœa, dysmenorrhœa engages our attention, a condition taxing our patience and knowledge, depending, too, on many and varied cases, for the relief of which some minor manipulations are required. From this to menorrhagia and metrorrhagia is but a step, as well as all the other hæmorrhages which may take place upon the sources of which we should be fully informed, and upon which we shall have to make a differential diagnosis. Here I would emphasize the value of an observation of Dr. Edis, "that where hæmorrhage from the uterus persists unnaturally, and where the ordinary medicinal agents fail in affording relief, and where there is no evidence of any condition external to the uterus, the cervix should be dilated, and the uterus explored."

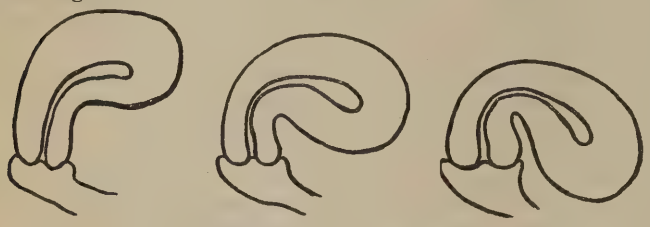
The methodical examination of the group of diseases I have thus described, conducted on sound principles, observations being duly recorded and deductions drawn therefrom in accordance with the strict rules of logic, will conduct the practitioner to a sound verdict, and enable him to differentiate between those conditions he can positively relieve or cure, and those which are abstruse and beyond his skill.

Next, if not in importance, certainly in point of number, we have to deal with another group—viz., uterine displacements—about which so much has been written, and on the proper treatment of which there is the widest disagreement. The number of pessaries figured in our surgical catalogues are not only an *opprobrium* to general medicine, but to the art we cultivate. It has always been a puzzle to me why men allow their names to be attached to modifications of instruments which in themselves do not possess the slightest utility, and none for the original purpose for which they are designed. Do we not attach an undue importance to the various deviations to which the uterus is necessarily liable, owing not only to its anatomical position, but to individual peculiarities? I may be here giving you old wine in a new bottle. Boulard, in his report on uterine deviations, 1854, states that in the fœtus there normally exists uterine flexion. In 107 cases he found 98 antiflexions. Aran found antiflexion in half the young people he examined, whilst Schultze, our latest writer, asserts that antiflexion is the normal condition of the uterus. The symptoms which are said to be associated with the various versions and flexions are so numerous that they really embrace all the common diseases of life, and if they depended on these displacements there are but few women who would be able to do without a pessary. The anomalous pains and aches to which women are liable can be legitimately traced to other causes than either version or flexion—viz., the hyperplasic or diseased states of the uterus and adnexa usually found in long-standing cases. I can understand the mechanical principle on which we act when we attempt to support a uterus which has a tendency to prolapse, or which is already prolapsed; but when we apply a pessary, which simply hangs loosely in the vagina after a few hours, in some of the conditions laid down in text books, we are, I contend, proceeding on unscientific lines, for I deny that there is an analogy between the pessary and the splint, save in prolapse, and I fail to see how a Hodge pessary can act as a lever. The subject of the use and abuse of pessaries is a very large one. Their condemnation, so far as their routine use is concerned, has been pronounced by some of the ablest gynæcologists of England and America; but, judging by the number of instruments shown to me by representatives of our surgical instrument makers, they must still be largely employed, for here the general principle comes true of supply being commensurate with demand. Schultze tells us, in his very philosophical and exhaustive work, "that the treatment of displacement of the uterus forms part of the daily routine of the general practitioner." This I believe to be true; but so far as my experience goes, with rare exceptions, and excluding prolapse, we can very largely dispense with the use of pessaries. This conclusion I have arrived at from two classes of practice comprising women in two distinct classes of society.

First. I have been struck by the number of women who suffer from aggravated forms of version and flexion admitted under my care at the Halifax Union during the last twenty years, and by the almost total absence of symptoms of distress on their part, and though I have a liberal supply of surgical appliances placed at my disposal, yet my pessary bill has been almost *nil* for this class.

Second. I have found the same condition in women of the better class whom I have had to examine for other causes, so that I have been forced by my own individual experience to the conclusions above alluded to. The old writers—Aran, Becquerel, Scanzoni, Nelaton—held this view, expressed in the following words, quoted by Nelaton from Scanzoni: "Flexions of the uterus have no importance, and are not followed by serious danger unless *they are complicated by some alteration in the texture of these organs.*" It is necessary to reposit the uterus, owing to well-defined malposition, but my experience is that a pessary will not *per se* keep it *in situ* after it is reposited, and that when the conditions are altered, as by posture, straining, micturition, defæcation, your pessary moves out of place. Rest and position will do what the pessary cannot do. If we look at the drawings in text books, and study them by the laws of mechanics, especially of uterine statics, it should be clear that the means employed are quite inadequate for severe retroflexion or antiflexion cases unless you have some descent. Shultze, though he advocates the figure-of-8 pessary, yet is almost as iconoclastic as I am. He says (p. 260): "There is still a very widespread misconception that the uterus can be brought out of an anomalous position by the pessary. This action was specially claimed for the Hodge pessary when it was brought out. No pessary in existence can do this; the normal position must first be restored bimanually; a pessary *may* afterwards maintain it." In prolapse it is different. Here we have a falling body which requires propping up. Examining the mechanism of this state we can understand that if we have a contractile vagina capable of sustaining between its walls any solid substance, rings, wedge, ball, that when the uterus rests on it, and conditions being equable—that is to say, the causes at work in promoting the prolapse being remedied—the heavy body will rest, and being supported, will cease its descent. But here we have to have one condition—vaginal walls sufficiently strong to retain the support. If they be flaccid or atonic, the support will give, and the uterus will still continue its descent until we have complete *procidentia*. All

this is elementary, but even yet not sufficiently appreciated. The means should be proportioned to the end. But even with prolapse this is not the case, for a heavy body like the uterus is but too frequently placed on a simple ring which cannot find support on the damaged columns, and the fancied security the patient has received is all chimerical; she is living in a fool's paradise, from which she is rudely wakened when she finds ring and uterus protruding from her vagina.



THREE CASES OF ANTIFLEXION.

TWO CASES OF EXTREME ANTIFLEXION.

THREE CASES OF RETROFLEXION.

Whether general practitioners, as a rule, possess a healthy scepticism as to the value of pessaries, I am not in a position to affirm, though I know from intercourse with many intelligent and experienced practitioners, that my views are not by any means singular. The paper contributed by Dr. Egerton Fitzgerald, and published in your *Transactions*, vol. iii., p. 37, gives countenance to my belief. Perhaps we may here have an opportunity of hearing some other opinions on the subject. What I consider wanting in our text-books are scientific or mathematical demonstrations on the dynamics of uterine displacements, in which will be shown the forces at work, the axes, the lines of resistance, the lines of replacement (the principle of the fulcrum and the lever are supposed to be connected with the pessary), definite instructions on the use of pessaries, on the best form, and plain reasons for using individual forms in each case, with rules for the guidance of patients. It does not help the student to see in a text-book the figures of a number of pessaries from which to select; this, I submit, only makes confusion worse confounded. I must here acknowledge that we have one text-book which fulfils many of the conditions laid down. I allude to Dr. Bantock's book on the "Use and Abuse of Pessaries;" but I venture to offer this criticism, that Dr. Bantock does not make sufficiently clear the dynamics of the pessary. I fully recognise the great aid he gives to the student by exposing in his illustrations and in his drawings the untenable position held by many teachers as to the action of the pessary. The specimen in my hand I removed a few days ago with great difficulty from a woman, who had worn it for a year. Her condition was most miserable when she came to consult me, and I could give case after case in which I had to remove not only box-wood ovals, but Zwanke's, Hodge's, which had been introduced and left to their fate in the dark cavity of the vagina. I do not forget that Shultze advises that his pessary should remain *in situ* for a year (p. 239)—a practice open to question. When we have placed one of these pessaries in the vagina, our responsibility does not end—this truth cannot be too strongly impressed on young practitioners. What is true of the simple pessary, is doubly true of the stem pessary. *Primum non nocere* is a sound surgical principle, not to be forgotten in gynæcology. The stem pessary cannot be used until we have straightened out the uterus—a process difficult when the whole uterus is involved. The stem can only fit as far as the flexion in such cases, and it must either lie partly in the vagina, or if pushed home, pierce the uterus. This point is not sufficiently emphasized.

Looking at the subject by the light of the papers read at this society, and the opinions of gynæcologists, I believe that in the future we shall derive more benefit from operative measures than we have done, and that in this direction we ought to move, especially as we may hope to have a more rational pathology, by the light thrown on the diseases of the uterine adnexa. Shortening the round ligaments, removing diseased ligaments and tubes, perineorraphy, and suture of the fundus, are philosophic conceptions, and indicate somewhat the lines of progress.

The examination to which we have to subject our patients, in order to duly estimate whether antiversion or retroversion, antiflexion or retroflexion, exist, often reveals to us conditions which would not otherwise be discoverable, and we are able to diagnose the existence of some of the various forms of tumour which are so plentifully brought before the notice of this society by our operating gynæcologists. In addition, we learn that behind the displacements there are other changes, as ovarian congestion, chronic metritis, hyperplastic states, cervicitis, adhesions, inflamed ovaries, the rectification of which is certainly as important as the change of position, and to some of which we can render effectual assistance by measures appropriate, but simple.

I have alluded to my experience at the Union Infirmary, and you will pardon me if I harp again upon an old string. In various papers, and notably in one published in a little book called "Hospital Management" (Keegan, Paul & Co.) I have pointed out the value of the clinical material we meet with in our union infirmaries, and I have formulated a scheme which, if adopted, would materially improve the status of these institutions. For teaching purposes our wards are admirably adapted, for students would see there the common diseases of every-day life, as well as rare and interesting cases. What is very much wanted is a closer relationship between the union infirmary and the general hospital; then the medical *personnel* would be brought up in point of number, and greater results would follow. I have 125 female beds in usual occupation; these include eight for confinements and eight for venereal cases. The geographical distribution of disease is a matter of interest,

as well as the incidence of disease amongst certain classes. Contributions to this common fund of knowledge might usefully come from medical officers of union infirmaries. Take, for instance, cancer, which is now so much, as the French say, "in the air." Such cases gravitate to the union infirmary. During the last twenty years I have only had six cases of uterine cancer, and four of cancer of the breast, in this infirmary. I have had a number of cases sent in with cervical ulceration, villous growths, syphilitic ulcers of cervix, which were supposed to be cancerous, but the recovery of the patients gave the negative to this. Again, how far are fibroids, ovarian tumours, prevalent amongst the working class in our northern manufacturing towns? I can give a partial answer for one town. It is remarkable that during twenty years I have not had a single case admitted, though I have been on the look-out for them. What influence has gonorrhœa on the production of tubal diseases? This is another question of the gravest importance. Medical officers of union infirmaries might be able to tell us something on this point; but, unfortunately, they can only partially help us, as they are not allowed to make *post-mortem* examinations.

The commonest affections in my infirmary have been menorrhagia, metrorrhagia, chronic endometritis, what is known as pelvic cellulitis (a name which embraces all the diseases of the uterine adnexa), various common affections of the vagina and vulvæ, which I need not enumerate. I have had only two cases of vesico-vaginal fistula; ruptured perineum I have rarely met with. In private practice I have been, I must consider, exceedingly fortunate in having not an almost absolute escape from this condition, but very few cases. One case I had many years ago. I was delivering Mrs. H—— with the long forceps. She was lying on an old-fashioned trestle-bed, and suddenly the bed gave way, and there was an indescribable scene. The woman fortunately escaped with a completely ruptured perineum, and I was taught a lesson on again applying the forceps to first make sure of the stability of the bed. She made an excellent recovery, the perineum being brought together by the old-fashioned quilled suture, and I attended the woman twice afterwards. Immediate suture secures excellent results, even though we have the lochia saturating the wound. Speaking of laceration, I may here allude to the subject of cervical laceration, upon which an admirable paper was read by one of your secretaries, Dr. R. T. Smith, and published in vol. i., p. 294, of your *Transactions*. I have attended 3,435 consecutive labours, attending the same women three, four, five, and even eleven times; so that I have had a fair opportunity of noticing the condition of the cervix. I have clearly made out its shape, and I can only say that it has been as varied as the patients' noses. I have met with the puffed and fringed cervix, the stellate cervix, the patulous and elongated cervix; but I have not found any tears of the severe nature I find described in American gynæcological works, requiring what is now best known as Emmett's operation. The slight lacerations heal, and I believe, as a rule, the cervix bears the strain imposed upon it just as well as the body of the uterus. I have been able to examine a number of uteri with complete *procidentia*, and I have been struck by the symmetrical shape of the os. I have now a patient under my care who has had five children. Through *mauvaise honte* she deferred seeking advice until she found the uterus protruding. In her case there is a circular, perfect os, though surrounding it there is a ring of denuded epithelium. She tried a ring, on her own initiative, but it was expelled each time she coughed. She now wears with great relief one of Dr. Barnes' cup and stem pessaries.

We are frequently consulted on the subject of sterility. Unfortunately, as a rule, our advice is only sought after some years of married life have passed, and I believe that this is the cause of our being able to do so little for the relief of sterile women. Bad habits have been indulged in for years; a desire for children leads to excess; mischief is done in the early days of married life which cannot be undone. I have notes of thirty-eight women, who through sterility have sought the best advice, but they have remained sterile. They all sought advice after years of married life.

The unsatisfactory state of the treatment of sterility I consider very much arises from what I have alluded to —viz., the deferring of advice to too late a period. "Hope springs eternal in the human breast," and women keep on hoping for conception, though they are suffering from disorders of menstruation, vaginal discharges, and much graver impediments to conception. But sterility is only a symptom. There is no universal formula or panacea which we can apply to each case. Slitting up the os or dilatation may in individual cases do good, but its general application is illogical. Each case has to be treated on its merits. Of course, if we use the metrotome for every case of sterility, we shall be certain to have some successes. We must not forget, too, that the husband frequently requires as much treatment as the wife.

We have entered on a new phase, however, and it is not now-a-days so much a question how to make sterile women fertile, as to make fertile women sterile. The fashionable vice of to-day is the prevention of conception through dread of the pains of labour, dislike to children, etc. This is not the place to discuss the subject, save in its relation to disease—does the system injure the woman? I do not wish to generalise from solitary facts, but undoubtedly, in a number of cases in my own practice the system has been attended by symptoms of uterine disturbance—that is to say, in cases where the semen has not been received within the natural *vas*, where Condom and retraction are the methods employed.

(1) In five cases there has been well-marked uterine irritability, with general *malaise* and cardiac disturbance.

(2) Uterine congestion, with vaginitis, prevailed in three cases, whilst in two I found ovarian tenderness. One case I give in detail: An old patient of mine, who had had four children, during an absence from home consulted a physician in the metropolis. She had mitral disease, but mitral disease can hardly be considered an impediment to having children. She recovered from her confinements very well. This physician told her that if she had another child she would die, and instructed her how to prevent conception, suggesting the worst of the methods—retraction. Life is valuable. The lady, who was of strong religious feeling, felt she was committing sin, but the husband consenting, they carried out instructions. For five years the practice was indulged in. There was such an aggravation of her condition that I was continually in attendance. After five years, through inattention to the instructions, she became pregnant. There were tears and alarm, and then I heard the history. Abortion was suggested by them as the only alternative to save her life. I at once put my foot down on the idea, and said that there was no necessity, as she ought to go on full time. My patient had faith in the physician who advised retraction, and murmured. So I said, "We shall see an obstetrician of repute in town,

and you can then have an independent opinion." I saw Dr. William Playfair with her. He heard the story, and said, "Go on till full time." She did so. I delivered her early, with the long forceps, of a fine girl, and she had not a bad symptom. The mitral disease still exists, but she has been since a happy, bright, contented mother, with a minimum of illness. I mentioned abortion as a suggestion. It is an easy gradation from preventive checks to abortion production, and few will question the ill effects of abortion on the uterine organs. I very much fear that we may now apply the satire levelled by Juvenal against the women of his time:—

"Sed jacet aurato vix ulla puerpera lecto,
Tantum artes hujus tantum medicamina possunt,
Quæ steriles facit, atque homines in ventre necandos conducit."
Juvenal, Lib. ii., Sat. 6.

Ovid was sufficiently educated to recognise the danger of criminal abortion from two aspects—the moral side and the health side—as the following lines prove:

"Quæ prima instituit teneros convellere fœtus,
Malitiâ fuerat digna perire suâ.
Hoc neque in Armeniis tigres fecere latebris,
Perdere nec fœtus ausa leona suos.
At teneræ faciunt, sed non impuné puellæ
Sæpè, suos utero quæ necat, ipsa perit." *Ovid*, 14 *Eleg.* Lib. ii.

Ovid has left us an excellent motto: "*Principiis obsta, sero medicina paratur.*" If we would remedy this evil of modern life, it must be by the application of this motto. If we can prevent this practice, I consider it is our duty to do so, and join in the condemnation against it pronounced even by pagan poets.

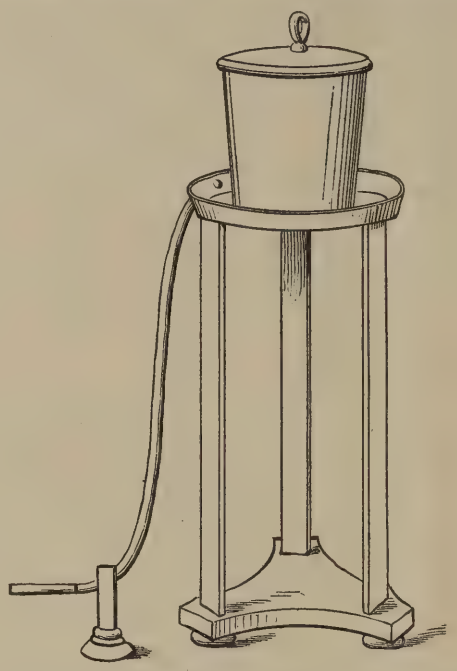
This perversion of natural instinct may be the outcome of civilisation, but it is only one of the many forms of perversion we meet with. The neurotic who wants a speculum passing daily may be familiar to many of you. She would require a paper to herself to fully describe her, for the sexual psychopathies are only symptoms of varied pathological conditions.

Preventive medicine is assuming a very great importance, as regards the other specialities, the eye, orthopædics, and, perhaps, in time, it may be possible for the general practitioner to apply his knowledge to the prevention of uterine diseases. This, of course, will require some education on the part of the public before they will bring to us their daughters. As a rule, menstruation is disregarded, and until some grave symptoms come on, as chlorosis, or excessive menstruation, we are rarely consulted. After marriage, when pregnancy takes place, all is left to chance, and the hygiene of the pregnant state is too little attended to. A very excellent chapter might be written on this subject.

I would recall to your mind the words uttered by our first president, the lamented Meadows, who died all too early, before the bantling he had helped in forming had commenced to walk. "I am," he said, "a firm believer in the use of drugs. To me practice would be shorn of its greatest attraction if I did not feel confidence in the things I prescribe." He asked for some experiences from general practitioners on the subject of the use of drugs—what they used, and why they used certain medicines. We have not had much information on the therapeutical side, so that a few words may bring out other observers to confirm or disprove my experience.

In the foremost place in uterine therapeutics I would place the use of water, hot or cold, plentifully administered by means of a proper *douche*, such as the one now in fashion. The proper introduction of the tube is most important, and it should be inserted to a good length, so that the water may be thrown on the os and surrounding parts. The ordinary enema cannot do this so well, owing to apposition of the vaginal walls and the intermittance and weakness of the jets.

The hydrostatic douche in modern use is not by any means a new invention. The accompanying drawing is



taken from Alibert's *Nouveaux Elements de Therapeutique*, vol. ii., p. 538, published in 1814. It was employed for the same purposes we now employ it, and even so far back as 1814 Alibert advises the practitioner to use, in addition to water, "various antiseptic substances, as wine and quinquinine," by means of this apparatus.

Apart altogether from purposes of cleanliness, we cannot too strongly impress on women the great importance of washing out the vagina. We can employ hot and cold water as a uterine sedative, for the relief of various inflammatory affections of the uterus proper, the vagina, and vulva. There are a large number of minor ailments, which cause considerable amount of pain and trouble, and which are absolutely dissipated by means of free douching. Exudations or hyperplasic states appear literally to melt down under the continued use of the hot douche. The cold douche is particularly serviceable in relaxed states, in women who have large flabby uteri and constant discharges resulting from atony. The douche will not dispel a fibroid tumour, cure prolapse, cancer, etc., but it will, in one or other form, be found beneficial and grateful to the patient by removing or washing away acrid discharges. The general term "leucorrhœa" is not only a very imperfect, but a harmful expression, leading too frequently to neglect of examination of the local conditions which underlie it, and which cause the discharges embraced under this name. Women have acquired a familiarity with the term "whites;" believing it to be a very simple symptom, they neglect seeking advice. The subject of intra-uterine injections is a very important one, and we shall frequently have to decide as to their advisability. In certain

states of the endometrium we can do no good unless we clean out the uterine cavity, and previous to this we should first dilate, and as we have now so many excellent dilators at our service this operation, with ordinary care, may be performed without risk. It is in the highest degree unwise to inject an undilated uterus. The cervical portion of the uterus is frequenly involved, and we have as a consequence a very common complaint, chronic uterine catarrh. Here the remedy I have most faith in is the tincture of iodine—an old remedy, dating back to 1830—combined with free washing and astringent applications, subsequently applied by means of the uterine douche. When stronger applications are necessary I resort to the tinct. ferri muriatis, first dilating the os, and then carefully injecting with a small syringe. Then I pack the parts with fine cotton-wool, allowing rest. The use of the nitrate of silver I have no experience of, as I have found the above satisfactory. Many other inflammatory states of the os are met with, which we have to contest by rest, sedatives, local applications—as leeches and scarification.

I regret to say we have very few uterine specifics, though we have a number of medicines which are indispensable to us to relieve symptoms. We have ergot, quinine, and strychnine, acting in various ways on the uterus. Apart from obstetrics, ergot finds a wide use in hæmorrhage depending purely on want of contractility, in cases of subinvolution. I have never found it to act as an emmenagogue; quinine and strychnine have the same power, though in a less degree. I know of no specific emmenagogue, not even permanganate of potash. Aloes will bring on the menses, but so in many cases will any purgative, when by relief of constipation, by this process of blood-letting, we have relieved the pelvic vessels; but this action has no relation to specificity. Women, through bad habits and feminine modesty, are very liable to constipation, and this is the case very largely with our operatives, so that purging is a very necessary commencement of all treatment. An overloaded rectum, and the straining induced thereby, are very largely responsible for minor uterine troubles. In the first rank I would place the ordinary sulphate of magnesia, prescribed in some form, by ourselves. I do not tell my patients to purchase Freidrichshall, Hunyadi Janos, or Æsculap. In the next place I would place cascara sagrada, as it has the valuable property of not constipating. Next in value are glycerine suppositories, when the bowels have been first well freed.

Without sedatives we could not well get on. We have morphia; then next to it in value conium, in the shape of the succus. It acts like magic in backache, and I place great reliance on it.

The bromides are essential in the irritability produced by disturbed uterine function. The older remedies, as castor, musk, valerian, and camphor, have no value. We have a wide choice in caustics; and for astringent remedies we can depend on oak, elm, bark, alum, sulphate of zinc, etc. Deodorants—misnamed disinfectants—are frequently necessary, and we have a plentiful choice.

I have tried a number of new remedies, as gossypium, used by negroes in South America, a so-called emmenogogue, but I cannot speak favourably of its action. Amongst the local agents the only one I have found of any value is the *Hamamelis*, or witch hazel. It is an agreeable and soothing astringent. Viburnum, hydrastis, and many other new remedies have been tried by me, but they have disappointed me. Vaginal tampons, or pads, are admirable contrivances, and may be relied upon in tender states of the cervix, for the application of dressings, etc. Of course we have to prescribe other remedies, such as tonics and the mineral acids, but the indications for their use are simply derived from general considerations, and bear no relation to special gynæcological practice.

Amongst the new remedies received, I must not forget to mention the bougies introduced by Messrs. Christie & Co. for application to the interior of the uterus, a sample of which I show. The construction is simple, and as the substance can be altered at will, I believe this will prove a useful little instrument. The general sketch I have given is sufficient to show how the general practitioner stands in relation to gynæcological specialism, and what a wide field he has, even without touching upon ovarian tumours, and the various diseases of the uterus and its appendages which call for absolute operative interference, for a class of cases which medicine cannot benefit, and for which the knife is the only remedy. It is essential that he should be able to diagnose these conditions.

During the last few years we have had to learn a new terminology—I allude to practitioners who have been in practice for some time—and I think it speaks well for the general state of knowledge of the general practitioner, that in his work on ectopic pregnancy and pelvic hæmatocele, Mr. Lawson Tait is able to place on record so many cases which had been diagnosed before operation by the general practitioners in attendance. What is wanted by the general practitioner is guidance and instruction on the diagnosis of obscure conditions. He is willing to learn, to keep pace with the times; and it is all important that he should familiarize himself with the symptoms of myoma, salpingitis, ectopic pregnancy, and the rest, because, in many cases, time is of the greatest moment, and an early diagnosis means a difference between life and death. Early operation is, or should be, a gynæcological maxim. From the many admirable text-books we possess on the diseases of women, he will learn a great deal, but I venture to think he will learn a great deal more by reading the admirable transactions published by this society, or by attending its meetings, for thus he will be kept up to the latest advances, not only in surgery, but in gynæcological pathology, diagnosis, and treatment.

Treating the subject from the general practitioner's side, I cannot conclude without a few words on our relation to the specialist. There cannot be anything antagonistic between us, even though I hold the view that as general practitioners we ought to be able to cope with the ordinary run of practice, because specialists themselves have been so liberal, instructing us by means of papers and text-books, opening our eyes, and making their special knowledge the common heritage of medicine. But our work must stop and have its limits; we must in cases of doubt, in cases abstruse, in cases requiring special operative measures, invite the aid of the specialist, aid which is always readily given, and aid which we should all the more readily invoke because you are not our competitors, as you have given us the wider field. It has been my pleasure and privilege for some years to have had many patients under various specialists, and I can say without flattery, that these consultations have been advantageous both to the patients and myself, and that I have found a high code of honour prevailing.

My experience is not singular. There is an antagonism of course between the general practitioner and specialists of a certain class. The specialist who finds fault with treatment when there is no ground for it, the specialist who makes an alteration in a mixture which simply consists in changing the colour, and who resorts to other artifices of the same kind, is naturally not popular. We know these men and their reputations, and we avoid them, but they are the exceptions. The specialist who carries on his practice on the pure lines of honour and candour, who is honest to his patient and to ourselves, is fully appreciated, and we have no antagonism to him. I have perfect confidence in those specialists to whom I send my patients, and I can always make a large selection. If the specialist deem it necessary that the patient should remain under his care for a certain time, giving his reasons, I consider that he is perfectly entitled to retain the patient, otherwise his hands would be tied, and he would simply be the slave of the practitioner—the patient would not receive what is her right—viz., the fullest benefit from the specialist's skill. As regards those patients who consult specialists without telling their family medical attendants of their intentions, the specialists are not bound by any code to inform the practitioner or to hand back the case, though many specialists do go beyond the rule—writing to the previous medical attendant their views of the case. The general practitioner does not himself object to take patients who have been previously attended by another medical man. He will not, it is true, take a patient when another medical man is in attendance, or when he is summoned in case of emergency: but when the patient desires to change, the code allows the practitioner full freedom to treat the patient who voluntarily comes, and who is not under the care at the time of any other practitioner. The golden rule of life is to do unto others as you would them to do unto you, and it would be paradoxical for the general practitioner to expect more from the specialist than he himself practises. We are apt to forget, in our zeal for medical etiquette, the rights of patients. The patient has a right to choose his medical adviser, general practitioner, or specialist. Our duty is, to act honestly.

If in general practice we are consulted about a case, and we cannot diagnose it accurately, it is criminal to carry the patient on for weeks or months without seeking other advice. If in special practice we magnify trifles and make mountains out of molehills, for the sake of extracting additional guineas, such conduct is equally criminal, and it is such conduct which brings a disgrace upon specialism. A patient of mine, without my consent, consulted a specialist. This specialist was of the vulture and speculum tribe, and he extracted seventy guineas from her, and would have had more, but chance enabled me to hear of his exploitation. A week's treatment under my care restored the patient. The diagnosis of the general practitioner is not always correct, but neither is the diagnosis of the specialist; so that charity, which covers a multitude of sins, may here find an application. And I believe it does, for the more highly educated a man is, the more disposed is he, in place of finding imperfections, to find excuses. There are many other points which I might have more fully considered, but these perhaps may be brought out in any discussion which may take place on my views. General practitioner and specialist have a unity of purpose, each working in their own sphere, but each working to a common end—the elevation of gynæcological practice and the relief of suffering women.

UTERINE MEDICINES.

By NAUNTON W. DAVIES, F.R.C.S.

IT can safely be said that no medicines are so disappointing in their action as those which are supposed to act upon the uterus and its appendages, and influence the menstrual habit in women. These remedies, so formidable in number, look very imposing when the long list is scanned; but is there not something in the multitudinous array suggestive of conscious weakness—of individual feebleness hidden in a crowd?

Borax, cantharidis, ergot, aconite, pulsatilla, caulophyllin, permanganate of potash or soda, peroxide of manganese, santonin, rue, savin, cimicifuga rac., sanguinaria, megarthes, pot. iodi, apiol, iron and the various cathartics.

Now, of all these remedies, have any of them shown a disposition to act consistently when given to different patients apparently suffering from identical troubles? It would be affectation to pretend that they have, generally, any such characteristics. Take borax as a sample. Given at one time it does good, without any unpleasant consequences, in the desired way; and the next time it is given, for the same purpose, it makes the patient very sick, and ends its eccentric usefulness at that distressing point. Cantharidis and ergot exemplify a similar want of consistent action, and when you give the one or other it is impossible to tell what the result will be. Then their failure is put down to a bad sample of these medicines, or to a want of diagnostic insight on the part of the physician. Aconite, it is true, can be depended upon to lower the plethoric state which sometimes interferes with the current of the natural function; but in this action it is a general depressant and not a special agent, although it brings about the same end as a classical emmenagogue would probably fail to produce. But if it is given for any specific effect it may be supposed to have upon the menstrual organs, under other conditions, it fails lamentably. But here the fault would be in the application, and not in the remedy, although its want of success under such circumstances would show the weakness of its claim to rank as an emmenagogue.

When the permanganates were introduced by Dr. Sidney Ringer and Dr. Murrell, they obtained a great many tentative believers, anxious to become permanent converts, and few were they who did not hope for great things from the use of these "new remedies."

But time destroys many illusions, and it is to be feared that this pleasant one has not been spared. It was claimed for the permanganate treatment that it "succeeded equally well in plethoric or anæmic cases." This parodoxical introduction to these remedies disposed some of the more sceptical to look upon their virtues with doubt, for, like mother Siegel's wonderful syrup, they pretended to work all-round miracles. First in the anæmic and then in the plethoric type of case, the permanganates completely failed in numerous instances, without one partial success to redeem them from the limbo of utter worthlessness as special uterine agents. This was my own experience, although I am aware that they have partially and sporadically succeeded in the hands of others, and notably in the hands of their sponsors. Their occasional success, however, does not make amends for their provoking and frequent failure, nor take them out of the list of unreliable remedies. Frequently, too, the disagreeable effect of permanganate upon the stomach is its most marked feature. Indeed, Dr. Marshall,

of San Francisco, suggests that it should be given with cocaine, cerium, and bismuth, to correct its tendency to produce nausea.

Peroxide of manganese is said to be more effectual than the salts of the metal; but as these partake of the general inconsistency of their class, and lead one to expect of them more than they enable one to realize, their constant action cannot be spoken of with any degree of confidence.

Santonin, introduced by Dr. Chèron shows the same characteristic indecision and waywardness in its effects. Dr. Chèron found good results following its administration in "amenorrhœa and dysmenorrhœa, more especially in cases characterised by anæmia, about the period of puberty." In similar cases, Dr. Amand Routh found it fail seventeen times out of twenty. How is this divergence of experience to be reconciled with any idea of consistency in the action of santonin as an emmenagogue? If it can be done, then the special virtues of santonin may be provisionally suspected to exist.

Rue, savin, cimicifuga rac. produce more certainly than any other agents, with the exception, perhaps, of ergot, a direct effect upon the uterus and its appendages, and specially stimulate the ovaries in a varying degree not always in proportion to the dose. In this way, the menstrual flow is sometimes brought about, but not always even in favourable cases, for an inflammatory state of the menstrual apparatus may be induced by the vigorous action of one of these agents, and yet leave the erring functions untouched. Here we have a fresh disappointment; the production of an effect, certainly, but not the effect desired. We have not to complain of a want of action, but of an uncertainty of action. Savin is notoriously unreliable in its effects, and I have known at least one death resulting from incautious self-administration of the drug, for the purpose of "bringing on the period."

Sanguinaria, megarthes (marsh trefoil), pot. iodide, apiol, iron, and the various cathartics have all had, and still have their advocates, and the most that can be said of them is that they are sometimes successful, and oftener unsuccessful, whether it be from the peculiarities of the case treated or from their own inherent defects. Of the long list of remedies noticed, there remain caulophyllin and pulsatilla, and of these much can be said of a favourable nature. Caulophyllin, the resinoid prepared from caulophyllum thalictroides, known in America under the various names of squaw root, pappoose root, blue berry, has been recognised in that country as a valuable therapeutic agent from very early times, and has been highly spoken of by many American physicians of note. Its name, "pappoose root," suggests the uses it was put to by the natives long before the cultured minds of our American cousins investigated its properties and catalogued its claims. There seems to be a general agreement amongst those who have studied its action, that its effect is chiefly felt by those motor nerves which are connected sympathetically with the menstrual organs, and that this action is of a sedative character, allaying that irritable condition of the generative system which so often lies at the root of functional irregularities. As a remedy in these derangements, in "irritable neurotics," especially when they are marked by disturbances in the sacral plexus, it has undoubtedly acquired a sounder reputation than most of its competitors, and deserves a permanent place in the select circle of approved remedies.

But its action, although often favourable when administered alone, is much more reliable when given in combination with pulsatilla (anemone pulsatilla, Pasque flower) which has long been known as a popular and effective remedy in uterine functional derangements. I remember not long ago being consulted by an old lady about a young friend of hers who was suffering from advanced anæmic symptoms, and had been the subject of long-standing amenorrhœa. She told me that the patient had been treated by several eminent doctors, and that they had failed to bring on the "period." "So I gave her some pulsatilla," remarked the old lady, "and brought nature to its senses." This story served to fix the remedy in my mind, and encouraged me to test its efficacy, which I have since done with good results. A few years ago it was well spoken of by Dr. Brunton and Dr. Gerard Smith as a sedative agent of much power in the treatment of inflammatory states of the testicle and spermatic cord, producing such rapid abatement of pain as to supersede even the necessity for morphine. As pulsatilla increases the beneficial action of caulophyllin, so the latter increases the action of the former, and it is, therefore, when they are both combined that we get the most perfect emmenagogue that our present state of knowledge has yet suggested. Indeed, it is not too much to say that this compound emmenagogue redeems from the charge of imposture the reputation of its dilapidated class.

In suitable cases I have used for a considerable time, and with gratifying success, the liq. caulophyllin et pulsatilla co.

It is not the purpose of this paper to enter into the treatment of the various forms of amenorrhœa and its allied complaints, but it may not be out of place to suggest that special remedies may fail when the cause is constitutional, and *vice versâ*. Many of the foregoing remedies have found their way into the special class of emmenagogues, because they have been used to treat some constitutional obstacle to the performance of the uterine functions, and because the imperfect function has been accidentally restored in this indirect way, they have come to be misnamed and misused as direct remedial agents. Hence, we have one good reason for the low estate to which the class has fallen. All of them may have their uses as indirect agents; while many of them may be used to the end of time, uselessly, if they are given upon no better ground than a simple faith in their use as emmenagogues. My own experience in the use of liq. caulophyllin et pulsatilla co. is most encouraging, and, while I urge with much confidence its use by my *confreres*, I would, at the same time, beg them to make their experiences known.

CONSANGUINEOUS MARRIAGES AND RETINITIS PIGMENTOSA IN CHILDREN.

By J. Oakley,

hon. surgeon halifax ear, eye, and throat hospital.

In the course of an investigation on deaf-mutism and consanguineous marriages, I met with several cases of retinitis pigmentosa in children of such marriages; and calling to remembrance the opinion expressed by Dr. Liebreich in his clinique at Paris, that more than one-half the cases that had come under his observation were children of relations in very close degrees of consanguinity, I traced the history of a few more closely; and the result was such that I place

the history of several cases before your readers, cases which I think strengthen the opinion of those surgeons who hold the view that consanguineous marriages are a frequent cause of retinitis pigmentosa. I do not propose to give you the clinical history of these cases, but the family.

M. W——, æt. forty-six, a pale, anæmic looking man, came to me in August, 1885. He was highly myopic, wearing —5. He had enjoyed fairly good health all his life, but knew that he had retinitis pigmentosa. He had been told so by an ophthalmic surgeon at Manchester twenty years ago. The disease had made very little progress until twelve months ago, when he found that he required to increase the strength of his glasses from —20 successively to —5, and that his sight was getting rapidly worse. His father and mother were first cousins. His father died at the age of fifty-six. His sight had been bad, and just before his death he was nearly blind. M. W—— believes that his grandfather's sight was very bad. His mother married again. By the first marriage she had two sons, M. W—— and a younger brother; by the second, three daughters. I have examined them all. The younger brother by the first marriage has retinitis pigmentosa. The mother and three daughters are perfectly healthy. M. W—— married a first cousin. He has had two children, a son and a daughter. The son, æt. fourteen, has retinitis pigmentosa. The mother and daughter's eyes are perfectly healthy. The son is also myopic. M. W——'s father's sister married a first cousin, and went to America. At my request he wrote to ask them to see an ophthalmic surgeon, with the result that the mother was found to have retinitis pigmentosa, and one son also out of six children.

E. G——, æt. sixteen years, rather a stupid, heavy-looking girl, was brought to me in May, 1886. Her sight was very defective, highly myopic, with —4, v = $\frac{12}{70}$. Upon examination, I found retinitis pigmentosa. She has one brother, æt. twenty-two, and one sister younger. They are both highly myopic, but had no trace of retinitis pigmentosa. Father and mother were first cousins, both dead; but the grandmother, who is living, says that they were both deaf, and had very defective sight. She herself has good vision, but she states that her husband's sight was bad, and that he was her second cousin. The old lady brought me another daughter to examine. She was myopic, but had no disease of the fundi. She, however, married a near relative, and says that she has five children, that some of them are strong, that one is deaf, and another has hip-joint disease.

H. L——, æt. twenty-seven, came to me in September, 1886. His sight had been bad since childhood; had been ordered spectacles in London when he was nine years of age, and his father was told that the boy had retinitis pigmentosa. The father was also affected, and had been dead for some years. His father and mother were nearly related. They had seven children, but he was the only survivor.

In the ordinary routine of hospital and private ophthalmic work I believe cases of retinitis pigmentosa are not common. Indeed, during the last three years, I have examined upwards of 5,000 patients, and have only met with nine cases; but I have, during the last twenty years, had a very extensive family practice, and I have carefully recorded the results of marriages of consanguinity. They are very interesting, and I hope on some future occasion to bring some of the facts before your readers. The result of my observations seems to me to prove most conclusively that consanguineous marriage is one, if not the chief, cause of retinitis pigmentosa; and I am certain that family medical men will do well to closely observe the lives of children of consanguineous marriages, more especially where it is known that the parents are not healthy. They will often find symptoms of disease which it is wise to recognise early. I do not mean eye diseases only, but the varied diseases that follow intermarriages of diseased parents; and when one sees a child about twilight groping about, and with no evident external eye symptoms, it is well to know quickly what is the cause, and if retinitis pigmentosa, judicious treatment will arrest its progress. I certainly do not think it is a disease beyond the reach of treatment. I believe that I have checked it in young children when the treatment has been carried out effectually. I do not mean to say that the marriage of perfectly healthy cousins may not result in healthy offspring. Modern investigation shows otherwise; but my experience, and that of several *confrères*, is that one or more children of such marriages are unhealthy; and I do think that it should be widely known, as interesting society generally, that retinitis pigmentosa is one of the many evils that are apt to result from inter-marriages with near relations.

ON THE LOCAL TREATMENT OF NON-SUPPURATIVE DISEASES OF THE MIDDLE EAR.[1]

BY ADOLF BRONNER, M.D.,

SURGEON TO THE BRADFORD EYE AND EAR HOSPITAL.

IT is quite a common thing to hear about non-suppurative diseases of the middle ear: "Leave them alone, do not interfere; no good can be done, and all treatment is useless waste of time and money." It is due to this wise doctrine that many people with disease of the middle ear do not seek medical advice till they are quite deaf, or very nearly so. The great secret of success in the treatment of diseases of the middle ear, on the contrary, is to try and get the cases at the very onset of the disease. We can then in most cases restore normal hearing, or at least arrest the progress of the disease.

The greatest triumph of otology in late years has been the fact that we have at last recognised how very intimate the relations are between the diseases of the nose and pharynx and those of the middle ear. In aural practice you very frequently meet with cases of diseases of the middle ear, which have been under treatment again and again. The disease always breaks out afresh as soon as the treatment is stopped. You examine the nose, find some disease of the mucous membrane; you cure this, and the disease of the middle ear returns no more. In all cases of chronic or recurrent diseases of the middle ear, we ought therefore carefully to examine the nares and naso-pharynx, and ascertain if there be any obstruction to the free passage of air over the Eustachian orifice, or if there be any source of inflammatory reaction. In the nares the obstruction may be caused by swelling of the mucous membrane, or by polypi. For the former we now mostly use the galvano-cautery, and for the latter the cold or hot wire snare. Forceps, formerly exclusively used for the removal of polypi, have now been universally abandoned. I always use the cold wire snare, and then burn the roots of the polypi with the galvano-cautery, to prevent recur-

[1] Paper read before the Bradford Medico-Chirurgical Society, March, 1889.

rence. The obstruction may be caused by hypertrophy of the osseous tissue of the lower turbinated bones, or by swelling or a tumour of the septum, which we have to remove by the knife or saw. It may be deviation of the nasal septum. This is usually situated in the cartilaginous part. It can be straightened by strong forceps, as suggested by Adams, Jurasz, Delstanche, and others; or the bulging part may be removed by the galvano-cautery or knife. In the latter case, if you first loosen a flap of the mucous membrane, and then cut out a piece of the cartilage, you can remove the obstruction without leaving any subsequent perforation.

In the naso-pharynx the obstruction is generally caused by hypertrophy of the pharyngeal tonsil, commonly called post-nasal growths. This is a very common disease, especially among children. At least 3 per cent. of children under fifteen suffer from post-nasal growths. The symptoms of post-nasal growth are very evident. The child cannot breathe through the nose, keeps its mouth open, which gives it a peculiar and stupid expression, and it invariably snores at night. The great importance of post-nasal growths is their relation to diseases of the middle ear. Of 198 cases of diseases of the middle ear in children under fifteen, which were under my care in 1887 and 1888, post-nasal growths were found in 101 cases, or over 50 per cent. Of 151 cases of post-nasal growths, 125 cases, or 85 per cent., showed symptoms of disease of the middle ear. I usually remove the growths with Hartman's curette, and in young children never use an anæsthetic. The operation is very simple, over in a few seconds, and there is not the slightest danger. If an anæsthetic be used, the operation becomes much more formidable and dangerous.

Chronic hypertrophic rhinitis very often causes disease of the middle ear. The milder kinds of treatment, such as the nasal douche, various kinds of snuff, etc., are of very little use. The only effective mode of treatment is to use the galvano-cautery. With the help of cocaine, this operation can be rendered practically painless.

Ozæna, or chronic atrophic rhinitis, very often spreads into the middle ear. These cases are obviously very hopeless. Of sixty-four cases of ozæna which I have seen and treated in late years, the middle ear was affected more or less in forty-eight cases.

In treating affections of the pharynx, the galvano-cautery is now largely used, especially in cases of granular pharyngitis. I also use Mandl's solution (iodine, iodide of potassium, and glycerine) for painting the pharynx.

Roughly speaking, we can divide the non-suppurative diseases of the middle ear into three classes: acute catarrh, chronic catarrh, and dry catarrh or sclerosis. It is often very difficult to say if the case be one of disease of the middle ear only, or if the internal ear be not also affected. Up to the present, we know of no very definite objective symptoms by which we could distinguish between the two affections. We know that in diseases of the middle ear, ærial conduction is more affected than bone conduction, and that high notes are heard better than low notes, and *vice versâ* in diseases of the internal ear. For the differential diagnosis we use high and low tuning forks and Galton's whistle. We usually first try "Rinne's test." You press a tuning fork on the mastoid process, and hold it there till the sound is no longer heard. Then you hold it in front of the ear. If the ear is normal, or if the internal ear is affected, you can hear the tuning fork in front of the ear, when you can no longer hear it on the mastoid process; Rinne is then said to be positive. If the middle ear is affected, you hear the tuning fork longer on the mastoid process than in front of the ear. Rinne is then said to be negative. If you place the tuning fork on the middle of the head, you hear it louder on that side on which the middle ear is affected or most affected. This is called Weber's test.

In cases in which there is much ankylosis of the ossicula you can hear much better in a loud noise, in a railway carriage or mill—so-called Paracusis Willisiana. In these cases there is obviously little hope of improvement. I saw a very evident case of this kind some time ago. A gentleman walked into my consulting-room, looked about him in a peculiar sort of manner, and asked me in a loud voice if there was a piano in the room. On my answering "No," he pulled out a small concertina, and began playing. At first I thought he must be slightly mentally deranged, and was much surprised when he said: "Please excuse my making this awful noise, as I can hear you so much better." As long as he continued playing, he could hear me fairly well; but as soon as he stopped, he could scarcely hear me at all.

In cases of acute catarrh, with much pain, we apply leeches and hot fomentations. Leeches are most effective if applied in front of the tragus, much more so than if applied on the mastoid process. Linseed and bread poultices often give rise to severe and even fatal suppuration and should not be used. Hewetson found that in cases in which there is much pain the glycerine of carbolic acid B.P. dropped into the external meatus often relieves the pain, and prevents perforation of the drum-head. If there be much bulging of the drum-head, we ought to make a free incision into the most prominent part. The bulging is generally found, not in the lower half, as one would expect, but in the upper and outer quadrant. If there be much secretion, which does not readily become absorbed, we incise the drum-head in the lower and outer quadrant. In cases of frequent recurrence of the secretion, we incise and syringe out the tympanum through the Eustachian tube. As soon as the acute pain has ceased, and not before, we use Politzer's bag, or the Eustachian catheter. This is of very great importance, as it prevents subsequent adhesions of the drum-head to the walls of the tympanum, which are otherwise very apt to occur, and as a matter of fact, do occur in most cases which are not carefully treated.

In chronic cases we now use the Eustachian catheter almost exclusively in preference to Politzer's bag. The immediate effect of the catheter is not always more marked than that of the bag, but the improvement in hearing lasts much longer. The catheters now in use are much shorter and smaller than those formerly used, and if the cocaine spray be applied to the nostrils the catheter can, with a little practice, be introduced without any pain or discomfort. Another advantage in the use of the catheter is that by the help of the otoscope you can in most cases hear if the Eustachian tube be open, or if there be any fluid in the tympanum. If you cannot hear the catheter (granted that it is in the proper position) there must be some obstruction in the Eustachian tube, either simple swelling of the mucous membrane or a structure, or the drum-head must be adherent or the tympanum filled with fluid. If it be simply swelling of the mucous membrane, this can be readily removed by passing cocaine or menthol fumes into the Eustachian tube through the catheter. Menthol dissolved in spirits of wine (20 per cent.), on cotton-wool, is introduced into one of Hartman's or Lucae's disinfection

capsules, and the capsule fixed on to Polizer's bag. The fumes are thus forced through the catheter into the Eustachian tube. Instead of Politzer's bag I use a double bag (*a* and *b*), as suggested by Lucae (fig. 1). It is attached to your button-hole by the hook *c*, and the end of the india-rubber tube (*d*) is fastened on to the catheter The advantages of this form of bag over the ordinary Politzer's bag are obvious. Sometimes you have to pass a probe into the Eustachian tube through the catheter. I use celluloid probes with a conical end. The probes are passed about three centimètres into the Eustachian tube, and ought to be marked to avoid the possibility of passing them too far, and thus injuring the drum-head or ossicula. Electrolysis has also been used to remove any stricture there may be in the Eustachian tube. We must be very careful to thoroughly disinfect the catheter after use. Not only can the germs of suppuration be carried from one person to another, or from one ear to the other ear of the same person by a dirty catheter, but what is of very great importance, syphilis can be, and frequently has been inoculated. The best and simplest method of disinfecting catheters is to boil them in water for about five minutes. I keep a large stock of catheters, and boil the used ones every evening.

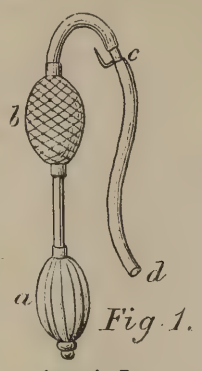


Fig. 1.
Lucae's Bag.

It is of great importance to know if the drum-head be freely movable. This can very readily be done by Siegle's pneumatic speculum. It ought to be tried in every case.

In cases of ankylosis of the ossicula, Lucae has suggested the use of a "pressure sound" (fig. 2). It consists of a

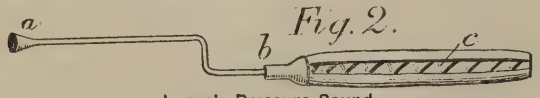

Fig. 2.
Lucae's Pressure Sound.

probe with an excavated end (*a*), which is covered with a thin layer of cotton-wool, and which is attached to a spiral spring (*c*) concealed in the handle. You put the end *a* on to the point of the short process of the malleus, and press the probe several times. In cases of chronic catarrh

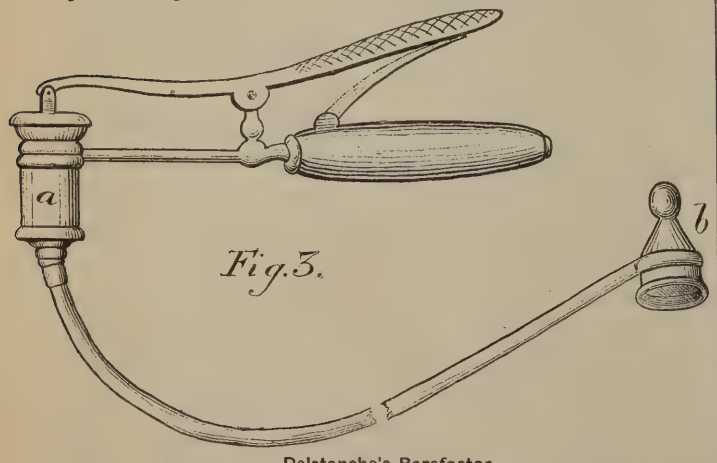

Fig. 3.
Delstanche's Rarefactor.

this is not at all painful. Delstanche, of Brussels, has introduced a very ingenious instrument for a similar purpose (fig. 3). By the help of a small air-pump (*a*) attached to a pneumatic speculum (*b*) you can either simply move the drum-head up and down (massage), or by increasing the vacuum break down any slight adhesions of the drum-head. The operation must be controlled by the frontal mirror. As far as my experience goes, this instrument is of very great use if used together with the catheter, but if used alone it does not seem to leave any marked effect.

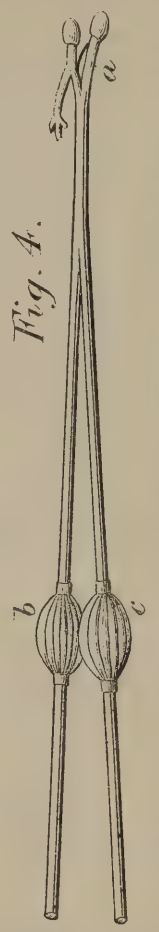

Fig. 4.
Ward Cousins' Bag.

Ward Cousins has suggested a modification of Politzer's bag by which he proposes not only to blow air into the middle ear, but also to aspirate air and fluid out of the middle ear. A nose piece (*a*) is fixed into the nostrils, then one bag (*b*) compressed with the left hand, and the other bag (*c*) rapidly compressed several times with the right hand, and then you let both bags suddenly expand at the same time. There is a spring in the bags so as to enable them to expand more suddenly.

If the drum-head is much indrawn, and the posterior fold very prominent, we often find that an incision through the fold improves the hearing very considerably. Unluckily the effect mostly passes off in a few days. If the drum-head be adherent we try to divide or cut round any adhesions there may be. If it be very thick, and the deafness well marked, it has been proposed by Schwartze to cut out the whole of the drum-head with the mallens. Kessel has proposed also to remove the stapes in these cases. Formerly the tensor tympani muscle was frequently divided, as suggested by Weber-Liel, but the operation has in late years been abandoned. Cholewa, of Berlin, lately recorded several successful cases.

Sclerosis, or dry catarrh of the middle ear, is the disease we dread most in otology. It is a very chronic affection, and often hereditary. The first symptoms generally are buzzing noises, followed by a very gradually-increasing deafness. Music and noises are often heard perfectly well when "speech" is only heard with difficulty. You frequently see people in concerts, or theatres, who hear and appreciate every note, and can at once detect any false note; but if you speak to them you find that you have to talk very loud if you want them to understand you. Sclerosis always affects both ears, but one ear generally begins first. The deafness in the second ear mostly increases much more rapidly than that in the first ear, and eventually becomes greater. This is a very curious phenomenon, and difficult to explain. The drum-head appears in many cases to be very little affected. Often it is of a milky grey colour; often very thin and atrophic. In the latter case we make numerous incisions, in the hope of thus causing it to contract and become firmer. In sclerosis the deafness is caused by degeneration of the mucous membrane of the middle ear, followed by ankylosis of the ossicula and thickening of the membranes over the fenestra ovalis and rotunda. In advanced cases the disease generally spreads on to the internal ear. The catheter is of very little use, and we have to rely on Lucae's pressure sound, Delstanche's rarefactor, combined with local treatment of the mucous membrane, and also with general treatment. All kinds of fumes and fluids have been suggested for injection into the middle ear—steam, chloride of ammonia fumes, iodine fumes,

ætherial oils. I have lately exclusively used menthol and eucalyptus, and have had very encouraging results.

Various fluids have also been injected—solutions of iodide of potassium, chloral hydrate, sulphate of zinc, carbonate of soda, pilocarpine. I use a solution of carbonate of soda, iodide of potassium, glycerine, and water. The fluid can either be injected through an ordinary Eustachian catheter, or better, through Weber-Liel's tympanic catheter. The latter is a thin indiarubber catheter, which is passed through the Eustachian catheter, and three centimètres beyond. The fluid is then injected into Weber-Liel's catheter with an ordinary Pravaz's syringe.

CASE OF GOUTY AND PULMONIC (?) EMBOLISM.[1]

By J. Gordon Black, M.D. Lond. (Harrogate).

The changes impressed upon ordinary pathological processes by the different diatheses, and by specific infections, constantly afford studies of profound interest to the busy medical practitioner. Often it is only the accumulated experience of years which prevents the physician being baffled by the very unusual guise in which some "old familiar friend" in the shape of disease has clothed itself. The keen eye and practical experience of a trained scientific observer is, however, happily enabled to work wonders in following up and elucidating nature's puzzles in pathology! For example, such light may be thrown upon an apparently obvious case of cancerous ulceration, necessitating the amputation of a valuable limb, as to drag out of its obscurity some mysterious phase of syphilis. Consequently a few big doses of potassium iodide put an end to further anxiety, and saved a valuable member to a useful life. Or it may be an aggravated biliary derangement, with threatening jaundice, which has obstinately resisted the most painstaking and varied therapeutics. Here an "open sesame," is found in the simple fact, probingly elicited, that the sufferer has spent his early years in a malarious country. The alterative treatment, which, indeed, seemed most appropriate, must now be combined with quinine, in order to carry the case to a successful termination. On the other hand, the patient may be approaching dissolution under the heavy, combined, weight of most serious symptoms. His heart, labouring even to a degree, is yet only able to produce a pulse of fifteen to twenty in the minute at the wrist, the beats being of the greatest irregularity. Breathing is laboured, or like the urgent gasp of a confirmed asthmatic; whilst a profuse bloody expectoration is being brought up by the hacking cough. Liver dulness reaches nearly to the level of the umbilicus, at the same time that the abdomen is distended by ascites, and both legs are anasarcous. At least half a pint of blood is frequently passed with the stools, and this has been going on for many weeks. Lastly, the urine is freely albuminous! The case looks perfectly hopeless, and may puzzle "even the very elect!" However, it turns out to be only another instance of the symptomatic vagaries of that *Deus ex machina*—gout! It is a functional disturbance, and capable of being removed by remedies, simple in themselves, but directed towards the central neurosis. The difficulty in diagnosis has been the recognition of apparently serious organic lesions, in various important organs, as merely the remote effects produced by a central neurotic disturber. Once the cause is recognised, the therapeutic way is opened to a happy and apparently wonderful cure.

To a Harrogate practitioner, the various phases of the gouty or the uric acid diathesis must always be specially interesting. The following notes respecting a case of certainly uncommon occurrence may therefore, I hope, prove acceptable to, and be profitably discussed by, this society.

My patient was a gentleman of good social position, about seventy years old, who, being a fellow of his college, and having enjoyed a good private income, had never needed to employ his faculties, either mental or physical, as a means of livelihood. He possessed in a marked degree the uric acid diathesis, but, as is not unfrequently observed in such cases, had never experienced an acute attack of gout, or even anything approaching this in character. Being of powerful physique, he had kept himself healthy by taking long walks, and making a business of fishing, shooting, rowing, etc. His main drawback had been the possession of an unusually sensitive nervous organization, accompanied by much difficulty in procuring sleep, unless under specially favourable circumstances. In later years his spirits had become so irritable and depressed as to produce aggravated hypochondriasis. He even frequently talked of his great dread of committing suicide. Being a man of religious surroundings and sympathies this was naturally most distressing to him. His sleeplessness also increased so much as to become a monomania. Lodgings had to be secured with special reference to quietude at night and the absence of striking clocks or crowing roosters; whilst the bed-room window-blind was made of such a thick material as would exclude every suspicion of light. Latterly, even with these aids, he was very much dependent upon the use of various sedatives for obtaining sleep, without which he speedily reached a pitch of irritability and excitement pitiable to witness. As might be expected, constipation was another of his enemies. Nevertheless, he was not at all inclined to be bilious, and did not suffer from many of the ailments peculiar to his diathesis. He had no dyspepsia, acid eructations, or pains in the stomach or bowels. The tongue was nearly always clean, or had only a slight fur at the back, and he was never troubled with hæmorrhoids. There was no palpitation of the heart, though when a little out of sorts its beats would become irregularly intermittent. The pulse, however, was very characteristic. Being about sixty to the minute, it was usually regular, excepting the occasional intermittency referred to above, whilst the beat was particularly full, and marked by very high tension. Shortness of breath was not complained of, and he was an excellent walker, and climbed hills with ease. Attacks of migraine, or neuralgia, were conspicuous by their absence.

Now the ordinary urine in this case was always highly coloured, very acid, and loaded with uric acid and urates; but it was abundant rather than scanty. After standing an hour or two the uratic out-throw was so large that, on tilting the vessel, thick lines of red sand could easily be formed at the bottom in any direction. The specific gravity was always high, and the urine invariably contained a distinct trace of albumen. During a sleepless night, or whilst under excitement, large quantities of pale urine of low specific gravity were passed, as in hysteria. Bile acids were increased in the ordinary urine, though not to any marked extent. If Dr. Latham's theory be true as to the imperfect transformation of albuminous matters in the liver, with the resulting production of insoluble uric acid, instead of the soluble urea,

[1] Read before the Harrogate Medical Society.

it occurs to me as strange that, in a case like this, there should be complete absence of anything like biliary derangement, or its symptoms.

Naturally the patient had a large appetite, and nothing came wrong to him. Though fairly abstemious as to drinks, a dinner of even aldermanic proportions seemed to cause no trouble, and produced no symptoms, beyond, perhaps, a temporary excess of lithates in the urine.

No doubt for years my patient had kept himself in good health by the large amount of exercise he had taken. Advancing age, however, must have very much curtailed its actual quantity, and probably deterioration began in the difficulty of getting rid of the bye-products of assimilation.

About two years ago he suffered severely from carbuncle at the back of his neck, and a few months afterwards lost a quantity of blood from epistaxis, which appears to have been stopped with difficulty. Soon after this he came under my care, when I found him considerably run down in condition. His complexion was pale and parchment-like, with a slight icteric tinge. Under a more liberal diet, and an allowance of flesh meat, which had been interdicted from fear of the hæmorrhage returning, he soon improved. During a course of the "Old Sulphur Well" quite a nest of gravel was passed. The concretions were about two dozen in number, and varied from the size of a millet seed to that of a small pea. Such a lodgment would be sure to cause very considerable reflex irritation, and certainly the mental symptoms became tranquilised, and sleep more regular afterwards. Judging from my own experience, this systematic flushing out of calculi, whether renal or biliary, is by no means an uncommon occurrence whilst the "Old Sulphur Well" is being administered.

My patient continued steadily to improve till he left Harrogate, in seemingly excellent health, for a man of his years, about the beginning of October, 1887. I did not see him again until the 31st March last, when he looked fairly well, and I did not notice that he had lost condition during the winter. The only treatment ordered was a morning draught of the "Old Sulphur Well," as an aperient. It has been necessary, thus far, to mention details in this case, in order to properly appreciate the more serious symptoms which now followed. On Tuesday morning, the 3rd of April, he called at my house in almost a frantic state of excitement, saying that while walking out he had been suddenly seized with a most violent pain in the right knee. He nearly fainted, but managed to support himself against some iron railings until he was able to move on to my house. On examination I found that the right knee-joint was already considerably swollen as in synovitis. The surface of the skin was not reddened, nor did its temperature seem raised. Evidently there was still acute pain, for the patient could scarcely bear the least movement of the limb. I concluded that embolism, of gouty origin, had occurred in one of the exedent vessels of the joint, and I had him removed to his lodgings, and put to bed. The knee-joint was carefully fixed on a back splint, and suitable soothing lotions were applied. He seemed quite helpless, and was dependent on the services of a man nurse. Though two very restless days and nights were then spent, the trouble continued to be limited to the affected joint, and no constitutional symptoms manifested themselves. At my visit on Thursday morning, pain and swelling had considerably subsided, and his recovery was evidently only a question of rest for a few days. About noon, however, of the same day, he was rash enough to get out of bed, in order to reach some article from a chest of drawers. His man servant, who was in the room at the time, suddenly heard a loud thud; and on looking round, saw the old gentleman lying full length upon the floor, apparently in a fit. Of course he rushed to give assistance, and called the lodging-house keeper and her husband, who were on the spot in a few seconds. The patient was quite insensible, and they at first thought him dead. However, on lifting him upon the bed, he seemed to breathe again. Meantime I was summoned, and fortunately arrived in a few minutes, just when consciousness had returned. A terrible alteration had taken place during these few minutes in the appearance of my poor friend! His face and body were blanched to a degree, and had all the aspect of a person having undergone a frightful hæmorrhage. Scarcely any pulse could be felt at the wrist, and, on listening to the heart, its formerly strong and regular beats were found replaced by a feeble fluttering. The breathing was laboured and gasping, whilst a clammy perspiration had broken out on the forehead. It clearly looked as if the sufferer had not many minutes to live. I lost no time in injecting half a drachm of ether into each arm and each leg. This seemed to rouse him a little, but I was alarmed to find that he wanted to get up to the night stool. I was afraid he would die in the effort to rise, but he insisted, and succeeded. Of course I expected to see that a large hæmorrhage had occurred from the bowel, but was agreeably surprised to find a large pultaceous stool of healthy character. Mr. Hunt, whom I had sent for, arrived about this juncture, and the patient was injected with ether as before, so that in the course of about fifteen minutes he must have received at least four to five teaspoonfuls of ether hypodermically. Some slight rallying of the pulse was now manifest, but the whole aspect of the patient was that of a dying man. On careful auscultation of the chest, the only physical sign discovered was decided dulness over the left lung in front, extending outwards and upwards from mid-sternum, and the præcordial region. Breathing over this area was, moreover, scarcely audible. On inquiry, complaint was made of a feeling of weight and oppression over the front and left side of the chest, but there was no acute pain, nor was there any cough or expectoration. Nervous, irritable, and even childishly timorous of slight ailments when in health, it was remarkable to see how absolutely calm he had become when death was staring him in the face. After two or three hours of imminent danger, during which life hung, as it were, in a balance, a genuine rally took place. The pulse began to improve, and the surface of the body became warmer. Gradually temperature increased, reaching during the night and following day 100° to 102½°. The pulse also rose to about 100 per minute, but it remained very feeble, and all its old fulness and tension were gone. I need not trouble the Society with details of convalescence in this case, but wish to point out that the dulness noticed over the left lung became less and less each day, and, as it did so, the breathing over the silent area increased more and more, until—about the end of the first week—the dulness had entirely disappeared, and respiration was natural again. About the same time the temperature also subsided to normal. However, the pulse was much slower in recovering tone. Even after a fortnight had elapsed it was far from being strong. Convalescence may be said to have been established at the end of six weeks, when something like the old characters were once more noticeable in

the pulse beat. Of course, I was for a long time in considerable fear lest exercise might bring about a renewed attack, but nothing untoward happened, and at the end of four months my patient left Harrogate in apparently his customary health. Though five months have since then elapsed, he remains well, I am glad to learn.

There was nothing worthy of remark in the treatment of this case, save perhaps the liberal hypodermic use of ether. This, I think, must be credited with having assisted in tiding over the serious crisis; though, of course, it is impossible to say that the *vires naturæ* would not have proved sufficient in themselves. The diagnosis is foreshadowed with sufficient clearness, I believe, in the following extract from Dr. Robson Roose's excellent monograph on "Gout." At p. 89, 5th edit., he says:

"In connection with the circulatory organs, gouty phlebitis requires to be briefly noticed. Inflammation of the veins, especially in the lower limbs, is somewhat liable to occur in gouty subjects, and either with or without acute attacks in the joints. The superficial veins are those most frequently affected; the inflammation begins very suddenly, and causes severe pain and tenderness. It may spread continuously, and may appear simultaneously in several veins. It sometimes disappears, and affects other veins at a distance. . . . . Symptoms of embolism have been known to supervene, with death from obstruction of the pulmonary artery as a result."

The above quotation seems to me fairly to compass the subject. The preliminary seizure of the right knee joint, accompanied by intense pain, and followed by swelling, pointed clearly to an embolic formation. Since fibrine is considerably increased in the blood during a gouty attack, it is not necessary to suppose a venous inflammation as the commencement of such a seizure. It seems to me more probable that a clot of blood is the initial error, judging by the extreme suddenness of attack. The subsequent and infinitely more alarming symptoms, I cannot explain on any other theory than that of a similarly sudden obstruction of the left pulmonary artery or vein having taken place. A clot in the pulmonary vein might be expected to cause rapid œdema of air cells in the left lung, accompanied by the important signs of decided dulness and loss of breathing over the affected area. The exceedingly slow disappearance of these physical signs, together with the more tardy recovery of the pulse (naturally one of high tension) seem to preclude the idea that such an attack could be due to a mere syncope!

Accidents, similar to the above, ending in more less sudden death, are, I believe, not uncommon in persons of the gouty habit. The manner of life of such individuals after the age of forty seems eminently calculated to bring about a catastrophe. Most people after middle age begin to circumscribe the amount of exercise to which they have been accustomed in previous years. This greater tendency towards inertia does not however materially curtail the appetite for bodily food of all kinds, which is indeed too often stimulated by the "pleasures of the table." Thus at a period when the physiological processes of secretion and excretion are diminishing in activity, a more importunate demand than ever is made upon their waning powers. The overtaxed system, therefore, becomes surcharged with its own waste products; the proportion of fibrine in the blood is dangerously increased; and in the resulting train of gout and its allies is apt to be included a mode of dying which is fearfully precipitate. Now, to eat seldom and sparingly, is the almost universal custom of those who attain to any considerable age. Even a somewhat free indulgence in alcoholic liquors appears to be better tolerated by the economy, and causes less trouble in excretion than a similar excess in taking solid food. People need not be ill because they are old, if only they would take care to adapt the mode of life to the constitutional change which years have wrought. The earnest physician, therefore, must never be weary of preaching moderation to elderly patients of the gouty habit. Though in a few cases the laying down of rigid rules as to particular kinds of diet may be required, yet for the majority I would feel inclined to place more faith in the prescription of two or three simple meals daily, together with plenty of fresh air, sunshine, and exercise.

FOOD AND DRINK.

By E. Bonavia, M.D., etc.

Has the quality of food and drink no influence on the present and future of a nation? If it has, then I propose here to endeavour to find out how far our knowledge on this subject can help us to decide what kinds of food and drink are likely to be best for us now and in the future.

Meat, vegetables, alcohol, and water, are largely used by large sections of mankind. Have we any means, from what we know, of speculating reasonably about what is likely to be the result of extensive changes in the food and drink of a nation? Whether one ought to be a meat or a vegetable eater, and an alcohol or a water drinker, seems to have very seriously exercised many persons' thoughts, and appears to be doing so still. Not very long ago, in contemporary journals, there appeared an article on "Scientific Temperance," and another entitled, "Instantes Tyranni." On the 30th of April, 1889, there was a discussion in the House of Commons regarding the *Abkàri* Department. It was stated that in India increased facilities for drinking spread misery and ruin among the industrial classes. It may not therefore be out of place to add a few ideas to the literature of vegetarianism and temperance.

Meat and Vegetables.—It will be fruitless to endeavour to go back to the origin of things, and investigate the cause of monads having branched off into the animal kingdom in one direction, and into the vegetable kingdom in the other. Nor would it be of much advantage to try and unravel the problem whether carnivorous food led to aggressiveness, or aggressiveness first led to a carnivorous diet. What I wish to do is to take things as they are now, and try if we cannot extract from experience some wholesome general notions about the value of these four great divisions of the ingredients that have built and are building up nations. I think it will be conceded that the carnivora, whether mammals, birds, or fishes, have more courage and dash in their nervo-muscular apparata than the herbivora. The former are more ready to attack and pursue, while the latter are more ready to run away. If a vegetable diet were as good in the race of life as a meat diet, it is not likely that the Hindoos would have been conquered by a much smaller number of Mohammedans. Nor is it likely that both would have been conquered again later on by a European power. There are many Indians, of course, who eat meat; but as a nation, they are vegetable feeders, with the addition of milk and "ghee." The Hamran Arabs are essentially meat eaters

(we might say *raw* meat eaters). The illustration at p. 254 of the "Nile Tributaries of Abyssinia" is sufficient to indicate the diet of these people. All their hunting exploits are mainly with the object of getting meat, and Sir Samuel Baker has borne witness to the courage, "elan," and marvellous prowess of the *Agageer*—the hunters of the elephant and lion on foot, with the sword! It is doubtful whether a vegetable feeder, even if he trained himself for fifty years, would be able to jump off a horse at full speed, and, sword in hand, hamstring the elephant, as these men are said to do. There is a *something* given to the blood, and thence to the nerves and muscles of the whole frame, by meat, which I believe is not to be got from any amount of bread, beans, and turnips, or other vegetable diet alone.

The Zulus and the Soudanese have shown such unmistakable tiger-like action in their encounters with the British, that without knowing what their regular diet is, I should incline to believe that they live mainly on meat; while, on the contrary, I thould say the mass of the Egyptian people live on a vegetable diet—probably bread, beans, pumpkins, onions, and dates, meat being beyond the means of the majority. It would be satisfactory to know whether this is so. If not, then to what was the cowardice of the Egyptians, and the leonine courage of the Soudanese and Zulus, due? Was it all due to constitution, without reference to diet?

The "Book of Health," by Malcolm Morris, lately published, at p. 169 has the following:—"Sir Francis Head, speaking of the Pampas Indians, in South America, says that they have neither *bread*, *fruit*, nor *vegetables*, but they subsist entirely on the flesh of their mares; that they wear no clothes, and that the climate is burning hot in summer, and freezing in winter." Speaking of himself, Sir F. Head says, that after living on Indian diet for three or four months, and riding all day, he felt that "no exertion could kill him." He was on horseback before sunrise, could ride till two or three hours after sunset, and he really tired ten or twelve horses a day. He said he was confident that this could "only be done on beef and water." I never heard of any vegetable feeder being able to do anything approaching this. One meat eater, in one day, was able to tire twelve vegetable feeders (horses)!

Now, we all know that what one person can digest, another cannot. In fact, this experience is probably as old as man himself, and has given rise to the adage: "What is one man's meat is another man's poison." Doctors have also told us that, in their experience, under-done meat is often more easily digested by a weak stomach than any other food. An instance has been given of a patient, who was sinking from weakness, and inability to digest any of the many kinds of food he had tried. A new doctor he consulted advised him to try an under-done partridge, which was found perfectly suited to the weak patient's stomach. Then we are also told that in cases of persons suffering from starvation, the best diet to give them at first is a small quantity of raw meat, finely chopped; because, under such circumstances, neither is the mucous membrane of the stomach able to secrete gastric juice, nor, even if it were, could the mucous membrane of the intestine suck up the digested food. The juice of the raw meat, it is said, is sucked up by the capillaries, without requiring digestion, and so helps by degrees to revive the starving frame. It would therefore appear as absurd to prescribe a vegetable diet for everyone, as it would be to prescribe a dose of castor oil all round.

It is not reasonable that people whose ancestors, for generations, have lived and procreated, and have been selected by nature, on a meat diet, can be benefited by, all at once, turning vegetarians (not milk, egg, cheese, and butter vegetarians, but *strictly* vegetarians).[1] I should say their nature would be gradually altered with the thorough change in their diet. Our being, it appears to me, is inseparable from our diet, as one of our surroundings, in spite of the theories of laboratory chemists. I feel certain that the lion would not be benefited by a similar change, although the originals from which all animals have come may, and probably must, have been strictly vegetarians. I think if a person is much benefited by a change from a mixed to a rigidly vegetable diet, it is probable that he was either in the habit of eating too much meat, or too much of both meat and vegetables. In such a case he would probably have been equally benefited had he only *restricted* his total diet.

It would seem more sensible to direct a crusade, not against this or that kind of food, but against the habit of eating too much, or more than one needs. To tell the truth, however, I don't think that it is so much the fault of over-eaters that they do exceed, although habit, no doubt, has a great deal to say in the matter; but habit even, philosophers now tell us, can be *inherited*. I once asked a friend who had the Darwinian theory at his finger's ends the following question: How is it that almost universally our appetites are larger than our actual needs? It would be clearly an advantage if the appetite ceased as soon as the system had had enough. After a few seconds' thought, he said: "In by-gone times, when food was not so easily obtained, it was clearly an advantage to the individual to eat more than was needed at the time. Those who could not over-eat would, at times, suffer from starvation, and might be extinguished in the race of life." It is probable, therefore, that our sins of over-eating may be due, to some extent at least, to ancestral imperative greediness.

Ancestral inherited defects can no more be extirpated by a stroke of the pen than the dog can get rid of his ancestral big toes all at once. They still assert themselves, now and again, as dew-claws. It is, therefore, probable that man will have to bear with gout and nightmares from eating too much for some time. They may be only the result of ancestral habits, and will be got rid of, in the course of evolution, as soon as may be possible.

Eating too much, however, may not be entirely the fault of either eaters or their ancestors. A good part of the blame might, perhaps, be placed on the shoulders of cooks, the refined art of cookery, and numerous cookery books. To show how much the latter may have to answer for, one need only refer to p. 184 of a noted Indian cookery book, entitled "Culinary Jottings for Madras," by Wyvern. That part of India is hot even in November, and therefore there is no excuse for extra food on account of a low atmospheric temperature. The reader will pardon my giving the details of a menu for luncheon from this book, because it is rather phenomenal, and may give us some hint of why people sometimes make themselves ill on a meat diet. The climate being hot at all times in Madras, there is not much opportunity for frequent or sustained muscular exercise. He says: "Having discussed your oysters, some half-dozen

[1] I know that now the term vegetarian has been extended to eaters of eggs, milk, cheese, etc. The objection to eating meat becomes absurd in case of the egg. An egg, one day, may be eaten by vegetarians, but the same egg, eighteen or twenty days after, when it has turned into a chicken, should not be eaten!

dishes or so may follow, carefully contrasted one with another, and by no means dinner-like in their order, thus: an anti-pasto of *hors d'œuvres*; seerfish fricasseed with cucumber; kidneys à la brochette, with potato chips; little ballotines of quail in jelly, iced; fillets of beef piqués, with horse-radish sauce, or crème d'anchois; maccaroni à l' Italienne; cold galantine of hen-turkey, or capon, delicately sliced, and handed round; a Ceylon prawn curry, swimming in creamy gravy, with pieces of vegetable-marrow associated with it; a *chaud froid* of snipes; fruits in cream; liqueur. To do the author justice, he adds: "This menu is obviously susceptible of the pruning-knife (one might say the saw and the hatchet also). Two dishes could easily be cut out, and cheese with 'green butter,' and hors d'œuvres again might follow the sweet dish!" I suppose the hors d'œuvres again are intended to re-excite the appetite for dinner! The very mention of that "Ceylon prawn curry, swimming in creamy gravy," for the climate of Madras, makes one feel the fat expanding under one's skin! The cook's mission appears to be to coax the appetite, and to "carefully contrast one dish with another," so as to leave one no chance of evasion. As to the hygienic part, that's the doctor's business. The cook seems to think that if you are made ill by eating too much, so much the worse for you!

We all walk erect on two legs, and, within certain limits, we all have pretty much the same outward features; but does anyone for a moment reflect that, in spite of all this outward resemblance, there are among men and women, not only *varieties*, but what would amount to *species*, and *genera?* So different is one from another in constitution, habits, ancestral derivations, and conditions of life, that to make the same rule for all mankind, in a lump, is like making the same rule for the elephant, the pig, the horse, and the donkey, because we happen to call them *Pachydermata*. I was once told by a person: "I listen to the doctor's advice and instructions with civility and humility, but when he goes away, I do what I think suits me best." How different are the circumstances of two persons. One his own master, in a cool climate, can travel about, change scene, amuse himself, and follow up his own tastes. The other, an official in a small station in India, with a large family in England, an earnest and conscientious man, who goes to his office at ten a.m. steadily, and sits in the midst of bad odours, with the doors open letting in the hot air, listening patiently to innumerable "lies" day after day, on which he is to give judgment, till four or five o'clock in the evening, the only relaxation after office hours being perhaps a game of tennis, not because he feels much inclined for it, but because, like physic, he thinks it is good for him. He returns home for dinner with a friend or two, *the only amusement he has* in the twenty-four hours, and the only one he has to look to till he either obtains furlough or privilege leave! Under such circumstances, a person whose dinner may be his only amusement, might think that life is not worth having if, in addition to its monotony, and daily discomforts, and helplessness, he is to omit meat and wine from his meals. That many eat more than is good for them, especially when the age of muscular activity has been passed, I have little doubt. At the same time it is one of the most difficult feats of the will to refrain from taking one bit more when one's appetite is still on the alert. When an act is of vital importance, such as feeding, it is always accompanied by a feeling of pleasure; other acts of still higher importance are accompanied with even more exquisite sensations. If this were not so, the act might be considered a bore, and might be omitted with disadvantage to the individual and the race. Is gout however solely the result of over-feeding, and not largely the result of worry, anxiety, and hard mental labour? Alfieri almost starved himself, and continued violent horse exercise to the last, because he was told gout was the result of eating two much and taking no exercise. He had hard mental work in writing his tragedies, and anxiety about their success; perhaps he may have also had domestic worry. The gout tormented him to the last! A simple rule would be: when you are taking active exercise, and the weather is cold, let your appetite have its run. When you are sedentary, and the weather is warm, draw in the reins *especially when your girdle warns you* that your "intake" is more than your "output."

A friend in India gave me some facts regarding his experiments in vegetarianism in 1882. He had given up alcohol for nearly eighteen months before he made this experiment. He thought that it meant living strictly on *vegetables;* so at first he took no milk, eggs, or cheese. He says: "I soon found that I could not digest a vegetable diet in this sense (of vegetables only), and the indigestion I suffered I still feel some of the effects of. At least my digestion has not been so good as it was before I made the experiment. Hard things, eaten slowly and well masticated, such as cocoa nuts, I found very digestible, while delicately cooked cauliflower (as he ate it quickly and it did not require much mastication), was often very difficult to digest. I found I could not take tea on a vegetable diet, as it prevented sleep at night." Afterwards it appears he continued the experiment with the addition of milk, eggs, and cheese. He says he then had easy work, and this diet made no dfference in his power of work or of playing tennis, etc. He says the sole reason for giving it up was that, as he did not devise the dishes himself (although he had a good cook), he found the diet monotonous, and was not cheerful over it. Well, the fact is, he did not like it, in spite of the eggs, milk, and cheese, and he had to make his meals apart from his family to some extent, as they ate meat, and he felt unsociable. He did not feel better or more vigorous on returning to a mixed diet, that is with meat.

There are some persons who, either from habit, or from preoccupied or agitated mind, or from dining too much alone, cannot eat slowly, and unless they keep their attention on each mouthful, during the process of mastication, it is swallowed quickly and *involuntarily*. Now considering that many have not even time to read a paper, and only do so *during their meals*, it is not very easy to see how they can fix their whole attention on the act of mastication and deglutition. To these I should say, a strictly vegetable diet would certainly mean mischief.

Alcohol or Water?—This has been a vexed question now for a long time. As long as the subject remained in the sphere of discussion only, and cases of misery from drunkenness brought to light, and endeavours were made to remedy them, the effort was commendable. But when associations are set up, with the view of putting a stop to the use of liquor, not only among those who abuse it, but also among those who don't, the whole matter becomes *un affare serio*.

Have those who urge *total* abstinence ever asked themselves what might happen if all the people of Great Britain became abstainers? Let us take a brief and rough sketch of some of the nations of the world, and classify them *alcoholically*.

1. We have the Americans, the Britons, the Germans, and the Russians—all four nations large consumers of alcohol—with a population bursting with energy, indefatigable with a restlessness, both mental and corporeal, and always on the look out for further conquests, both in the mental and physical worlds.

2. Then we have Spain, France, Italy, Greece—all consumers of alcohol moderately, but all more or less fond of the "*Dolce far niente*" life, or in other words the majority of these people would appear to think that life is hardly worth having, if you have to bother yourself too much about it. The French probably consume more alcohol than the other three, and may be for that reason more energetic.

3. We finally have the Turks, and all the Mohammedan world, and the Indians. The majority of the former are total abstainers, and the latter so to a great extent. Well, not many would think that the position of the Turks, and other Mahommedan people, or that of the Indians, is to be envied. Turkey can do nothing; has been cut up over and over again; is only kept up by other powers, and as a nation, appears to be in a state of intellectual stagnation. India is only being spurred on by the British. Left alone, it would fall a prey to some energetic alcohol drinking power.

I read somewhere that a stranger observed a Turk squatted on the edge of a low wall in a street. He was smoking his pipe, and appeared to be engaged in some deep thought. The narrator went up to the Turk, and asked him what he was thinking of. The latter looked up with astonishment, and said "Nothing!"—as if he meant "What a silly question to put!" Well, this is not a bad illustration of what is stated to be the life of the Turk. He appears to have no intellectual life whatever, unless it be, perhaps, of warped notions; and, considering the advantages he commenced his career with in Europe, his collapse must have some very deep-seated, and continued cause. In Fyzabad, there is a *Ghât* in the "Guptar Park." I was one evening standing on the steps of this Ghât, looking at the setting sun, beyond the wide expanse of the river "Ghâgra." The brahmin in charge of the Ghât came up, and I began to talk to him about the setting sun. Then I said, "This is a very nice place, what do you do all day long? He replied, "*Nahàte, pooja karte, aur khana khàte—ye tin kâm!*" I bathe, I say my prayers, and I cook and eat my dinner—*Voila tout!* This is another type of a total abstainer. Neither the Turk, nor the Indian, appears to have any intellectual life whatever, and the worst of it is, neither the one nor the other seems to *want* it. With some exceptions, both are of an indolent nature, and their indolence may be owing to the want of alcohol. If any intellectual life is dawning upon them, it is probably among those who either openly or "quietly," now and then, take a drop, for I certainly would not call any Mohammedan or Hindoo *total abstainer*, simply because he *said so*.

The majority of both these people may think that "enough for the day is the evil thereof." This would be pleasant enough if it did not entail having some other nation's yoke on one's neck. Now does this apathy come from the want of alcohol, acting through generations, or not? That's what one would like to know; and if all Britons became total abstainers, would they eventually become as apathetic as the Turks and Indians, and would they then think that, if life requires all this bother, it is not worth having, and would patiently submit to be conquered by any energetic alcohol consuming nation, that would think that trouble worth taking. The question may be an *urgent* one. Have the proportion of total abstainers and vegetarians *already* leavened the British nation, to such an extent, as to make them careless of what may happen? This seems a most important subject for a searching inquiry on the part of any Temperance Association. It would be rather a poor consolation for Great Britain to find that, with its beer and roast beef, its energy and intellectual vigour—the talk of the world—had also gone, and that the end would be "it does not matter!"

Some might say that this intellectual apathy does not proceed from want of alcohol, but from climate. I should reply, however, that the northern Turk and the Afghan have not a warm climate, therefore their want of intellectual "go," cannot be due to the effects of a warm climate. Moreover, why are the British in India or anywhere else not intellectually apathetic? They live in the same climate as the Indians. I may then be told that the Turk, although an abstainer, makes the finest soldier in the world, enduring, patient and obedient. I did not say that want of alcohol will also prevent muscular development and the other fine qualities of the Turkish soldier. We have many examples of endurance and obedience, without alcohol, in the animal world. All I mean is that want of intellectual energy, and the absence of a restless spirit, would appear to have some connection with total abstinence, and I contend that it is of importance to know whether, by giving up liquor, we shall bring ourselves, by degrees, to believe that after all leaving things in God's hands is the proper course, and that any effort on our part is of no use.

The teetotalers I have come across have had more or less exaggerated views on religious matters, and it is not improbable that this may be the cause, in a great measure, of the fanaticism of the Mohammedans. I should not though, as I said, put down every Mohammedan as a total abstainer simply because he said so. There are Mohammedans and *Mohammedans*, and not a few who drink, but as a people they are no doubt generally abstainers. If I were asked for a recipe to make a man acquire exaggerated views about religious matters, I should feel inclined to recommend the trial of "stopping his liquor." In Sir W. Muir's "Annals of the Early Caliphates," p. 458, I find, "The interdict against games of chance, and the prohibition of even the moderate use of wine (ordinances in themselves not altogether devoid of merit) have tended to aggravate the moroseness, gloom, and gracelessness of Moslem life in public, resulting from the banishment of the female sex."

Amusement, with something to make one laugh, acts as a tonic to the nervous system, and in the absence of something comical to laugh at, or be amused with, a moderate amount of alcohol, independent of its other useful qualities, appears to open a window in the brain, through which the mind, so to speak, can readily see the comicality of a subject. This effect of alcohol alone—that is of making us cheerful—is of immense value to us. What priceless comfort it is to be able to close the window on the gloomy side of life, and open that on the bright cheerful side. Without this means, a life of competition, worry, disappointment and vexation would be unbearable. If taken in moderation (each according to his own idiosyncrasy) I do not know any other drug which would have the same beneficial effects all round, without leaving any disadvantages behind, to interfere with the renewal of the struggle for life on the morrow.

(*To be continued.*)

FEMORAL OSTEOTOMY FOR THE CORRECTION OF DEFORMITY RESULTING FROM HIP-JOINT DISEASE.[1]

By A. P. Morgan Vance, M.D., Louisville, Ky.

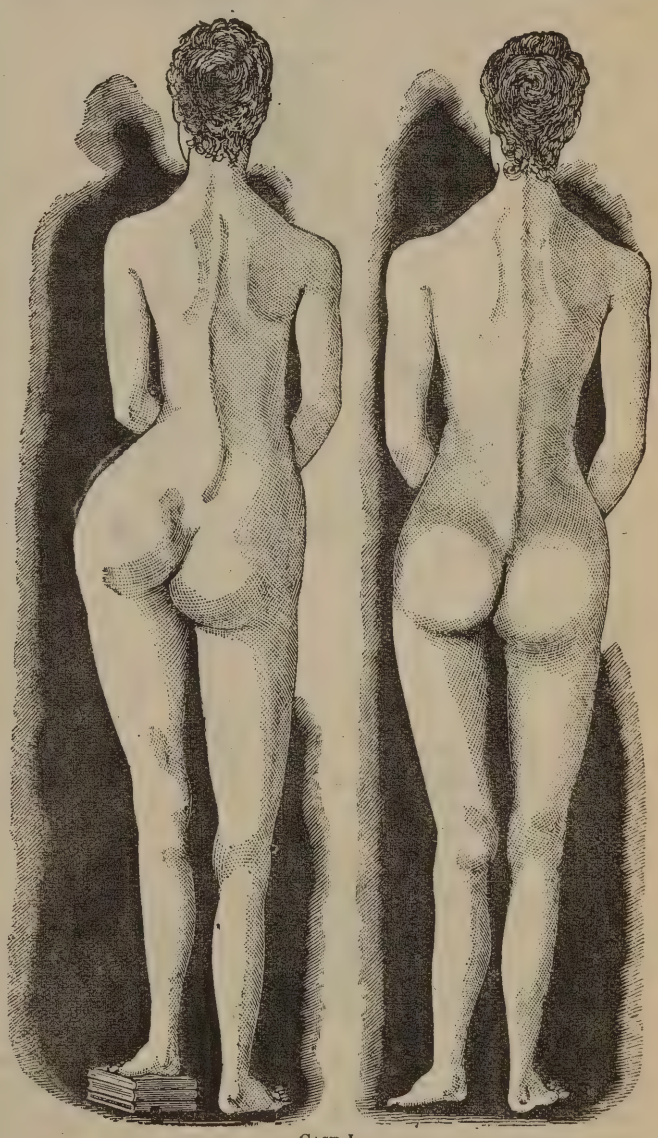
In the part of the country from which I come we have to deal with more of the different deformities resulting from neglected cases of hip- and knee-joint diseases than are met with in the larger cities, where greater attention has been given to the treatment of this class of troubles in the earlier stages. It has been my fortune to treat a number of these unfortunates, and it is to relate my experience in a clinical way that I am here to-day. There are one or two points I wish to emphasize. While in New York, a little over a year ago, I spoke to a distinguished surgical friend concerning subcutaneous osteotomy, and was astonished at his saying he had never mustered sufficient courage to do this operation; that he always made a large open wound, so that he could see what he was doing. This was a new idea to me, as I could not see any reason for the additional work. I have broken a number of bones subcutaneously, and have never had a feeling of any doubt of exactly what was being done, and have never had a single mishap, every case in its progress being practically a simple fracture. I freely confess that I will break a man's femur subcutaneously with as little misgiving, as to the outcome, as I would divide his tendo-Achilles.

The procedure will be described during the relation of some eight cases of femoral osteotomy, all the patients having practically reached adult life, the justifiability of the operation having been proved by the results. Of the eight cases to be reported five were operated upon for deformity the result of hip disease, and the remaining three for deformity following disease at the knee. The latter cases have proved to me how much better it is to correct, by a bone section, deformity existing at the knee along with slight motion and the patella fixed, than it is to interfere with the formerly diseased joint in an effort to better the condition. Cases No. 2 and 6 have been reported before in the *New York Medical Journal*, but, to complete a series, I will refer to them again as illustrating the advantage of subcutaneous osteotomy.

Case 1. *Subtrochanteric Osteotomy (?) in a Young Woman æt. Sixteen.*—Carrie H—— came under my observation first in the spring of 1883, giving this history:—Two years before she had been attacked with acute pain and evidences of inflammation about the left hip. She was under the care of skilful surgeons in the town where she lived, in a north-western territory, who repeatedly aspirated a large abscess which formed, the sac being located on the outer side of the thigh. The abscess finally healed, and, under tonic and constructives in bed for nearly a year, with weight and pulley attached to the limb, and sand-bags also used to keep the limb in the best position and the joint at rest. Notwithstanding their extreme care, the hip became stiff, as is often the case in extreme adduction: so, when she began walking, there was a practical shortening of four inches and a half or five inches, and, of course, a very marked lateral curvature of spine and obliquity of pelvis.

[1] Read before the American Orthopædic Association at its second annual meeting. Published by consent of Dr. Vance.

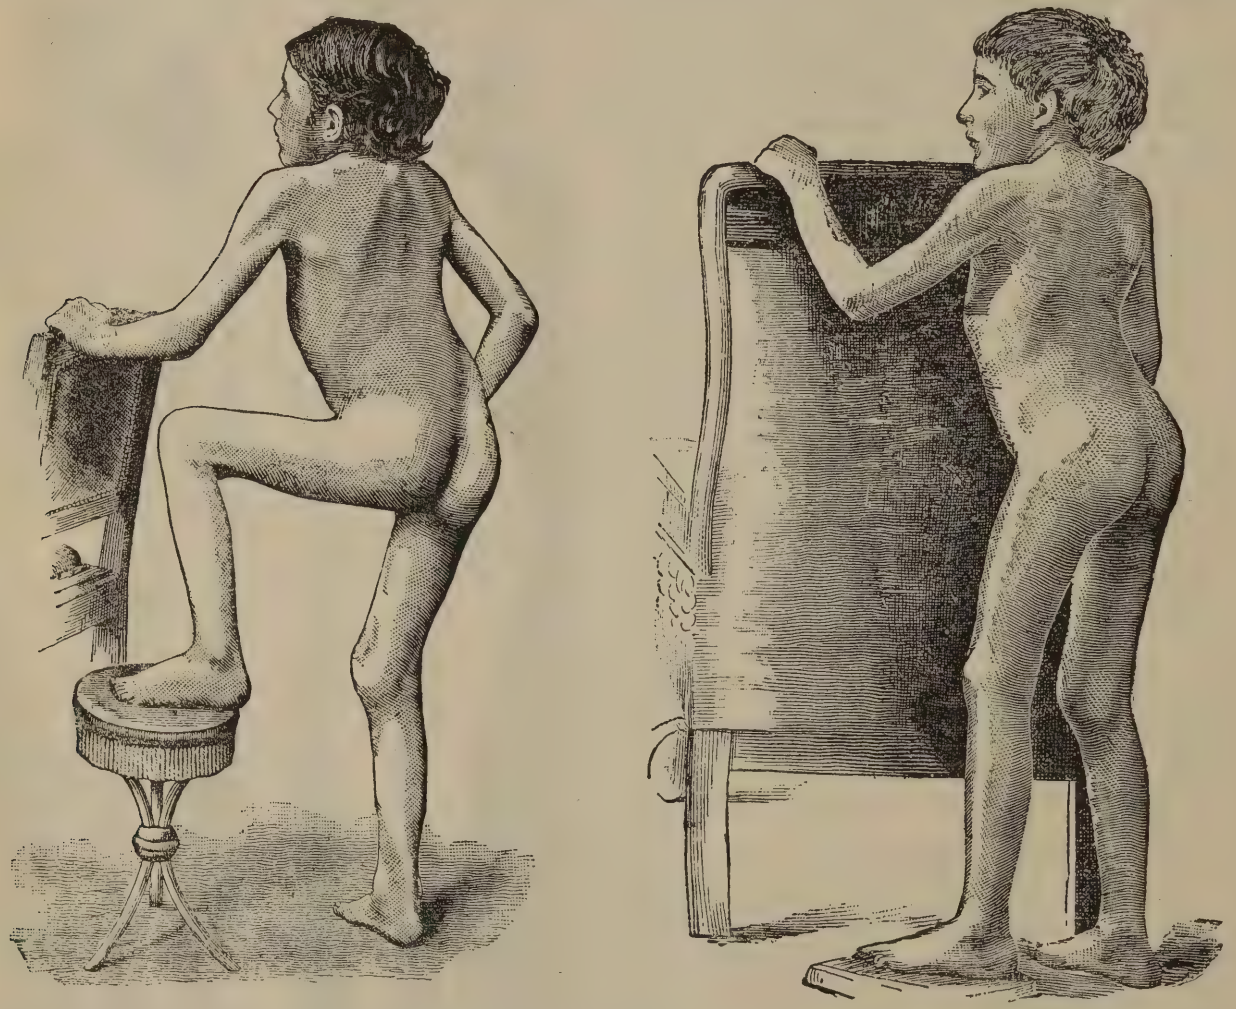
For the relief of this deformity the parents brought their daughter East, and, after a thorough examination, I advised non-interference, but told them, as they were going further east to New York and Boston, to see surgeons at each place. They did see Dr. Sayre and some Boston surgeon, who agreed with me that there was bony ankylosis at the hip, and the result was too good to be interfered with. But, after three years had passed and the girl had reached womanhood, the deformities grieved the parents very much, and, after communicating with me, who had hinted at bone-breaking



Case I.

as the only chance of correction, they came East again, and on April 16th, 1886, the bone section (*c*) below the trochanter was done as follows: A firm, well-padded block of marble was pressed against the inner side of the thigh as high up as the perinæum would allow. A very sharp, narrow chisel was pushed through the soft parts, the blade in the axis of the limb, the skin at the same time being drawn forward. When the bone was reached, the chisel, being

turned, was driven through until the hard substance on the opposite side was reached; this was partially divided; the chisel was then slightly withdrawn and directed posteriorly and then anteriorly. Without withdrawing the instrument, an effort was made to complete the fracture by using the block for the fulcrum and the femur as a lever, an assistant fixing the pelvis firmly to the table, the patient being on the right side. This failed, even after great force had been applied, for the reason that the adduction was so great the fulcrum could not be placed opposite the weakened point, but below. Further work with the chisel was then done. she was allowed to walk without crutches, the limb being restored to a position which let the foot reach the floor; at the same time the pelvis was horizontal. After she had walked very well for a week, using a cane when on the street, the mother noticed a tendency toward the old position when she was tired. Upon examination, to our utter astonishment, we found considerable motion at the hip joint on this side, which allowed the limb, from prolonged habit, to drop into adduction. The question arises, Were we deceived in thinking the bone was broken, or was the marked deformity corrected entirely by the renewal of



Case 2.

The instrument became very firmly fixed, a loud snap being produced when it was moved. All present believed it had been broken, but, on withdrawing it, to our relief all of it appeared. The effort to fracture was repeated, and the bone gave toward further adduction; then very easily, when force was applied, toward abduction. The deformity was completely overcome, and the limb was encased in plaster-of-Paris. Not a bad symptom arose during the after-treatment. She was able to be up in a rolling-chair by the fourteenth day and walked on crutches by the eighteenth, when a lighter tar board splint, reaching only to the knee, was substituted for the heavy plaster-of-Paris. At the end of the sixth week motion of what was undoubtedly a fibrous ankylosis? I lean to the latter opinion, not believing that the deformity could be so easily overcome with a fracture. The fact that the chisel was withdrawn destroyed my guide to what took place at the site of its introduction. As the result is, the patient is much better off, being relieved of the short limb and lateral curvature, with a movable instead of a stiff hip.

CASE 2.—June 11th, 1884, H. C——, æt. nine years, the subject of spinal caries and true hip disease, both long since spontaneously cured, the hip being ankylosed by bone at an angle of less than 90° with the pelvis, the disease in high dorsal region, which took up most of the power

of compensation in the lumbar spine. This boy could stand with difficulty by holding on to his left knee and right hip, but could not walk, his mode of locomotion being on all-fours. The patient was an inmate of the Methodist Orphan's Home, and ready consent to the operation was obtained; and, on the date mentioned, it was performed in the presence of the visiting physician of the institution and several other professional friends. The patient was anæsthetized by Dr. Senteny, and the operation was performed just as in Case 1, except that tenotomy of the muscles going to the anterior superior spinous process of the ilium was in addition performed when, without much difficulty, the limb was brought down and fixed in plaster of Paris, 90° of deformity being overcome. The wounds were dressed with compresses of absorbent cotton, and the case was treated as one of simple fracture, going on to conclusion without a bad symptom, the boy being able to walk at the end of five weeks. He walks any distance without difficulty, using an elevated shoe to compensate for about an inch and a half shortening of the affected limb.

April 3rd, 1881.—This boy is seen and examined. He has discarded the high shoe and can walk remarkably well. He has developed in a generally way very much, having attended school regularly since the operation, four years ago, and takes part in the different sports of the other boys without any difficulty with his limb.

Case 3.—April 6th, 1888, Nick M——, æt. fourteen years and a half, from near Versailles, Ky. A case of old hip disease which had been cured for six or seven years in malposition. The left thigh was flexed to about 90° with the pelvis and adducted very much, making this limb practically four inches and a half short, including an inch real shortening from a pathological dislocation. There was very slight motion between the femur and the pelvis. The boy walked by aid of a cane with marked limp, and became very tired when he undertook to go any distance. There had been an abscess, and a deep cicatrix was present below the trochanter. Osteotomy was performed just as in the preceding cases, and tenotomies were done of all the muscles resisting abduction and extension. The limb was placed in a plaster-of-Paris splint in a position of abduction, so that the inch and a half real shortening would be compensated for by the obliquity of the pelvis resulting when the limb would become vertical in walking. There was no mishap during the after-treatment, and the patient returned to his home at the end of four weeks with a protective splint of leather, which was worn for a week longer and then discarded.

September 7th, 1888.—Boy examined again. He walks with remarkable ease and comparatively little limp. When standing, he rests his weight on this limb. Has three quarters of an inch added to his shoe. The motion at the joint has allowed the abduction to be almost overcome, and the pelvis is nearly horizontal. The whole limb has been greatly developed in the five months since the operation, and the patient is in much better general condition. This is the first case of deformity of the hip with motion remaining that I have corrected by osteotomy. As I stated in the opening of this paper, I should prefer this to interfering with the formerly diseased joint.

Case 4.—Jennie H——, æt. fifteen years, came under observation on July 1st, 1885, in the female surgical ward of Louisville City Hospital, where she had been operated upon for a supposed fistula in ano. Soon after this I was asked by Dr. Douglas Morton to treat the case for a deformity the result of an old hip disease. The left limb was found greatly deformed, the girl being unable to get the foot to the ground. The femur was flexed to angle of 90° with the pelvis and completely adducted. There were a number of old scars about the trochanteric region, and the examination under chloroform proved the joint to be ankylosed by bone. There was a sinus along the left side of the rectum, and the ordinary operation by incision had been done without any good resulting. On careful examination, it was discovered that the source of the discharge was an old fistulous tract through the buttock towards the joint site. I considered there must be dead bone at the bottom of this, though none was discovered. By Nélation's test the thigh was estimated to be an inch and half short. I determined to correct the angle of deformity despite the existence of the discharging sinus, as the patient was in excellent general condition, and I felt sure I could break the femur below the trochanter without disturbing the old joint. On July 20th, 1885, in the presence of several of the attending staff, I did the operation just as described in Case 1, except the fulcrum, instead of being placed opposite the point of entrance of the chisel, on account of the extreme adduction, had to be placed posteriorly in the region of the gluteal fold, and consequently the difficulty of applying force was greater and the fracture harder to complete. This was done, however, without very great trouble, and the limb brought into the best position for future use, after tenotomy of all the muscles in the adductor region which showed any resistance; also the muscles going to the anterior superior spinous process of the ilium which became tense when extension was made. The limb was then fixed in plaster-of-Paris from the toe to the umbilicus. There was no bad symptom, and the patient returned to her home on the fourteenth day, after the application of a lighter splint, which was removed two weeks later, and moderate use of the limb commenced July 30th, 1888. The patient has rounded off into complete womanhood; gives a history of having had no trouble with the limb; can walk any distance without difficulty. The sinus still discharges watery fluid in small quantities. She wears an elevated shoe of an inch and a half; little or no limp. I advised her to have the sinus laid open and scraped before getting married, which is contemplated.

Case 5.—June 7th, 1886. Miss T. H——, tailoress, æt. thirty-two. This woman had been the subject of true hip disease when eight years of age. At the same time there was disease of the right wrist and the shoulder of the same side, small pieces of bone being exfoliated. The right hip was the one affected. It was about the worst-looking deformity of the kind I had ever seen. The femur was flexed to the last degree, and completely abducted; the knee could not be extended beyond a right angle, adaptation of the flexors having taken place during the twenty-two years. She had walked on a popliteal crutch. The pelvis was obliqued to the right, and the spine greatly curved. The patient had been an eye-sore to me for years on the streets, and finally was referred to me by Mr. Mathews, an artificial-limb maker, to whom she had applied for the repair of her crutch. On the above-mentioned date I divided the right femur below the trochanter and restored the limb to a position to be used to the best advantage under all the circumstances in walking after the fashion of other people. Both hamstrings were divided, and the muscles attached to the anterior superior spinous process of the ilium also, great force being neces-

sary to bring the limb down; the skin on the anterior aspect of the thigh looked glazed, it was put so much on the stretch. A plaster splint was applied, as in the other cases. Convalescence was uninterrupted so far as the firm union of the bone was concerned, but there was a tendency to swelling of the leg, together with anæsthesia of the parts supplied by the anterior crural nerve for six months or more.

Examined September 7th, 1888. She is in better health than ever before, and can walk long distances without using a cane. Has no trouble of any kind with the limb. She wore for awhile a shoe on the right foot, of an inch elevation, against my advice. She now wears an ordinary shoe. The limb was left in sufficient abduction to compensate for the actual shortening and part of the obliquity of the pelvis.

CASE 6.—A. B——, æt. seventeen years, came under observation in November, 1884, for treatment. There were the history and the evidence locally of an old inflammation of the left knee-joint, dating back to early childhood. The limb was greatly deformed, and he walked with painful inconvenience. The knee was found with very little motion, flexed at an angle of 135°, the leg being very much rotated in its relationship to the thigh; there was combined with this marked genu valgum. The compensating deformity of the foot was quite great, and walking painful. The procedure of dividing the bone was exactly as in the preceding cases, the final steps being much more difficult because of the limited motion at the knee, and the fear that it might be further damaged if too much strained by the use of the leg as a lever; but I succeeded by having the upper part of the bone fixed by a very strong assistant, then, grasping the condyles in both hands, with the application of sudden force downwards, using the same fulcrum as before, the fracture was completed, and the deformity overcome, after tenotomy of the external hamstring tendon. The limb was dressed in plaster, and went on to firm union as a simple fracture. The young man now walks anywhere without difficulty, and is the possessor, comparatively speaking, of a comely limb, a compensation of an inch and a half being added to the shoe.

CASE 7.—Mr. N——, clergymen, æt. thirty-two, had been the subject of inflammation of the right knee when a child, resulting in a permanent deformity, very much like that described in Case 6—flexion, combined with rotation of the leg on the thigh, and knock-knee. He came, he said, to consult me in regard to the possibility of having the deformity overcome, as it was particularly awkard in a public speaker. I proposed bone-breaking as a possible remedy, and after some dissension he consented. His consent was more difficult to obtain because he had consulted with an eminent surgeon in Virginia, who had warned him against letting anybody meddle with his knee. On May 10th, 1886, the operation was commenced just as in the preceding case, the bone being completely sectioned, however, without the use of manual force. Hardly had two strokes of the mallet being given before a complete fracture was produced. I anticipated a retardation in the process of repair, but no trouble was experienced, and in the usual time he was able to use the limb. I saw him on the street in April last, and he walked with little limp, and if it had not been for this, one would not notice anything the matter with him. While he is standing there is no reason to suppose him at all lame. His limb gives him no trouble.

CASE 8.—April 15th, 1888, John S——, æt. fifteen, telegraph operator, Hopkinsville, Ky. The deformity, a repetition of that in the two preceding cases, was the result of an inflammation of the right knee of only three years' standing. The procedure was carried out as in Cases 6 and 7 with the same result. He returned to his home on the sixteenth day wearing a posterior leather splint. There has not been sufficient time passed since the operation to determine the result in this case, but I expect just as useful a limb as in the other cases.

Cases 6, 7, and 8 illustrate how much good can be done by a bone section in a class of cases that, in my hands, have been very unsatisfactorily treated in any other way unless excision is done. You have a knee in which the pattella is fixed with flexion, rotation of the leg on thigh, and genu valgum, without the saving clause of bony ankylosis of the tibia to femur, but with limited motion, with no control of that motion. The history of these patients as to the utility of the affected limbs is always the same—constantly recurring pain and disabling at the least mis-step or stumbling of the toe. Any movement which puts a strain on the crippled joint brings about the same result, calling for a return to the cane or more often to the crutch. By a bone section and the substitution of an angle above for that at the knee, and at the same time rotating the leg, we place the tibia and fibula in the same axis with the femur, and restore the foot to a position much better suited for walking. By the improved relationship the intermittent strains are prevented and adaptation of the ligamentous structures allowed to take place, a firmer and much better joint being the result.

REMARKS ON JENNER AND VACCINATION: A STRANGE HISTORY IN MEDICINE.[1]

By H. H. TAYLOR, F.R.C.S.

NEARLY a century has now elapsed since Jenner published his "Inquiry into the Causes and Effects of the Variolæ and Vaccinæ; a Disease known by the name of the Cow-pox." Since that time he has had many opponents, but, with a few exceptions, he has had the entire support of the medical profession. Many men maintain that the truth of his statements are now firmly established and "outside all controversy." But it cannot be denied that there is a feeling gaining ground in the profession that there are many of his statements which require careful investigation. Many honest and disinterested thinkers are ready to admit that the subject is not in a very satisfactory condition; and that the time is not far distant when a thorough and impartial enquiry will become obligatory. Dr. Creighton's last work is anything but reassuring. If the statements which he makes are true, then must medical men seriously reconsider their position. If, on the other hand, they are false, it is time the profession should at once brand them as such, and protest most emphatically againt one of its members publishing statements which are calculated to do much harm. The work is avowedly written for the public, and Dr. Creighton would justify this action by maintaining that the profession turns a deaf ear to all criticism, and dogmatically asserts that the subject is now "outside all controversy." That such is the case no one will deny.

(1 By Charles Creighton, M.D.)

Dr. Creighton has been charged with "undermining Jenner's character." Let us see if he can justify his action.

Dr. Creighton objects to Jenner having, on his title page of the "Inquiry," styled cow-pox "variolæ vaccinæ." Now, as this work has been characterised as a "model of scientific investigation," it is only reasonable to expect that Jenner will produce evidence in it which will render that statement practically a demonstrated fact: otherwise he had no right to call cow-pox variolæ vaccinæ; still less to head his "Inquiry" thus. The only reasons we can find for this piece of fiction (Dr. Creighton characterises it as a "master-stroke of boldness and cunning") are, first, certain stories of country people that cow-pox protected against small-pox; and a few cases in which persons who had had the natural cow-pox were said to be proof against variolous inoculation. The question of how far variolous inoculation is reliable as a test will be fully treated of later on. Secondly, a supposed resemblance between the two diseases. He constantly talks of the value of experiment; yet he himself never made any experiment to see if cows could be inoculated with small-pox; nor did he try to infect them by bringing them into contact with variolated garments. He never relates one single instance in which cow-pox had caused an outbreak of small-pox. "There was no candid or overt attempt in the body of his essay to justify that daring innovation. Most of his readers from that time to this have hardly realised that it was an inoculation at all, for the reason that Jenner adroitly left his title-page to justify itself."

He got sadly mixed up between horse-pox and grease. Grease is a very chronic form of eczema, associated with much thickening of the heels, non-contagious, and bears no resemblance to horse-pox. Yet he dogmatically asserted[1] that cow-pox never arises independently of grease; and to show how much reliance should be placed on his observations, he minutely describes at what period of the disease the virus is most active.[2] In a foot-note he adds, "It is easy to procure pus from old sores [grease lasts for months, and is said by some to be hereditary] on the heels of a horse. I have often inserted it into scratches, made with a lancet, on the sound nipples of cow, and have seen no effects from it than simple inflammation." This last fact would, surely, have set most men a-thinking; but not so Jenner. The amount of scientific thought which he really brought to bear in conducting an experiment may be estimated, when he tells us he seriously endeavoured to produce grease (which he believed to be a specific contagious disease) in a young horse, by keeping it shut up and fed on beans!

It may come as a surprise to some people that Jenner could have made such statements, but, perhaps, if I narrate his cuckoo story it will help to explain how it was possible. The following is abstracted from his paper on the "Natural History of the Cuckoo," read before the Royal Society, 13th March, 1787, and published in the *Transactions* for that year. "The nest was placed so near the extremity of a hedge that I could distinctly see what was going forward, and saw the young cuckoo [less than a day out of the shell] in the act of turning out the young hedge-sparrow. The little animal, with the assistance of its rump and wings, contrived to get the bird upon its back, and clambered backwards with it up the side of the nest till it reached the top, where, resting for a moment, it threw off its load with a jerk, and quite disengaged it from the nest. It remained in this situation a short time, feeling about with the extremities of its wings as if to be convinced whether the business was properly executed, and then dropped into the nest again. With these (the extremities of its wings) I have often [how often?] seen it examine, as it were, an egg and nestling before it began its operations; and the nice sensibility which these parts appeared to possess seemed sufficiently to compensate the want of sight, which as yet it was destitute of."

The first impression on reading the above little story is one of amusement, which, however, quickly gives way to a feeling of depression, when it is realized that the paper was written as a scientific communication to the Royal Society; and that Jenner declared he had "often" seen similar crimes committed, when, in fact, "the behaviour of the young cuckoo was, on his own admission, new to him on the 19th of June, 1787, by which time the hatching season was about over for that year, and his paper was sent in and printed before another season." It reminds one of the remarks which the celebrated naturalist made to his friend, when he told him he had seen a marvellous shower of frogs from the sky. "It is fortunate," said he, "that you have seen it, for now I can believe it. If I had seen it myself I should not have believed it."

That cow-pox is variola vaccine is more than doubtful. On the face of it the diseases are so unlike that it would require very weighty evidence to establish their identity. Evidence, which in a scientific enquiry would be accepted as proof, has never yet been produced. The few experiments by which it is said cow-pox has been produced by variolous inoculation will not bear investigation. The French experts, who are no mean authority on this question, ridicule the notion; most of our leading veterinary surgeons do the same. Professor Crookshank, in a letter to the *Lancet* (March 9th), challenged anyone to produce one jot of evidence to prove that man ever infects cows, or that cows have ever caused small-pox in man. Up to the present time no one has answered him.

When Jenner went up to London, in 1798 to push forward his discovery, he took some cow-pox lymph with him, and gave a specimen to Mr. Clive, Surgeon to St. Thomas's Hospital. Clive having heard what severe and protracted ulceration Jenner's lymph caused,[1] intended to use it as an issue over a boys' diseased hip joint. He wrote to Jenner,[2]—"The inflammation arising from the insertion of the virus extended to about four inches diameter, and then gradually subsided without having been attended with pain or other inconvenience. The ulcer was not large enough to contain a pea, therefore I have not converted it into an issue as I intended." Jenner reproduced this letter as a testimonial in his "Further Observations" (p. 128), but he omitted the sentence commencing "The ulcer," and inserted instead "There were no eruptions." His reasons for doing this are obvious. In his hands, cow-poxing had caused such dreadful ulcerations, that he had almost been forced to abandon his discovery, as he did not like the sound of the word "ulcer." Moreover, Woodville had discovered an outbreak of cow-pox in London, and, by selecting the lymph early, before ulceration had advanced, had obtained a much purer strain than Jenner, and one which did not cause such unpleasant

[2] Baron's *Life of Jenner*, i., 152.

ulceration. He was, therefore, somewhat eclipsing Jenner, but, as he carried on his experiments at the Inoculation Hospital, many of his patients were brought into contact with, and contracted small-pox. The small-pox eruption which followed was, quite unfairly, attributed to his vaccine lymph. In proof of this, Jenner sent some of Woodville's lymph into the country, and found it so satisfactory, neither causing eruptions nor bad ulcerations, that he quietly distributed it as Jenner's lymph, at the same time not omitting to disparage Woodville's own stock.

What should we say of a man who, reproduced a letter, and quietly altered it to favour his own case? Had Jenner also forgotten the cuckoo tale when he wrote to Ingenhousz: "The truth, believe me, Sir, in this and every other physiological investigation which has occupied my attention, has ever been the object which I have endeavoured to hold in view."[1]

Now most people would expect that a scientific and honest worker, when investigating a question of so much importance, yet of such great difficulty, would court criticism, and when facts adverse to his theory were fairly brought under his notice, would give them as great a prominence in his publication as his own observations. Let us see how Jenner acted.

Dr. John Sims, an eminent man of the day, brought the case of a Mr. Jacobs, of Bristol, forward. He had twice had cow-pox and afterwards twice contracted the small-pox. Jenner called him a "snarling fellow," and accused him of "harsh and unjustifiable language." Percival, of Manchester, wrote to Jenner: "But a large induction is yet necessary to evince that the virus of variolæ vaccinæ renders the person who has been effected with it secure during the whole of life from the infection of small-pox."

Dr. Ingenhousz also brought to his notice an indubitable case where a cowman was infected with cow-pox, but afterwards being inoculated with small-pox, he took the disease. "A great many small-pox marks came out, and he communicated the infection to his father, who died of it."[2] Jenner, however, explained away this case, and similar ones,[3] by affirming that the disease was "spurious cow-pox!" Dr. John Fawsett,[4] of Horncastle, and Dr. John Stevenson,[6] of Kegworth, narrated equally bad results. Mr. Ward, surgeon to the Manchester Infirmary, "congratulated mankind" on the success of cow-pox, which was as follows: "Only one of his cases resisted variolation after being cow-poxed—namely, case viii. Three cases took small-pox in the clearest way after being cow-poxed (Nos. i., ii., and iv.); four cases resisted vaccination, and likewise resisted variolation; one case resisted vaccination and received the subsequent variolous infection; two cases were apparently variolated in the first instance by misadventure." Many more such cases were brought to his notice, and he began to be extremely worried for an explanation. At last a brilliant idea occurred to him. The vaccine lymph was, of course, "spurious."[6] "All cavilling, therefore, on the mere report of those who tell us they have had this distemper, and are afterwards susceptible of small-pox," can now be explained away by denominating them "spurious." He promised to depict real cow-pox, but never did so. And that lucky hit of Jenner's is still found useful; only, instead of saying the lymph is spurious, vaccinators state that all cases of failure are due to imperfect vaccination, or to bad marks, and so all "cavilling" must cease. We now come to what is the most difficult and most delicate part of the whole subject—viz., how far Jenner's attempts to variolate patients who had been cow-poxed can be relied on as proof that they were protected. Dr. Creighton maintains that effective variolous matter was never used by Jenner at all.

To appreciate the real significance of this statement, it is absolutely necessary to know what variolation really amounted to at the end of the eighteenth century; and consequently Dr. Creighton has gone somewhat fully into this question. His conclusions are, briefly, that by careful selection, only very slight local effect was produced, and in most cases practically no fever or anything else that could even confine a patient to the house. Now it is beyond dispute that in most of the cases that were variolated to test vaccination, some local pustulation did occur. If the table which Ceely gives,[1] to prove that his subjects were protected by vaccination from being variolated, be carefully scrutinised, it is at once apparent that such results were obtained as Dr. Dimsdale boasted he could produce in unvaccinated persons by his method of variolous inoculation. To fully appreciate, however, the weight of evidence which Dr. Creighton brings forward in support of his case, it is necessary to carefully read his book, and also to refer to the works bearing on this part of the subject, which were written about the time when Jenner was alive. In short, he entirely discredits Gatti and Sutton's "new method" as a test of protection. He says: "We come, then, to this extraordinary result, that the very same degree of small-pox infection—namely, the local pustule alone, or the local pustule followed by an abortive fever and a few abortive pimples, which had come to be reckoned a sufficient manifestation of the disease when inoculation was an end in itself, was now reckoned an insufficient manifestation, and, in fact, an evidence that the infection had not taken at all, when inoculation was done after cow-poxing, and with a view to test the alleged antagonistic power of the latter against small-pox."

There can be no doubt that Jenner recommended and practised the Suttonian method. On several occasions he urges that the variolous matter should be carefully selected, and the inoculation "managed so as to prove perfectly decisive."[2] Further, "A very respectable friend of mine, Dr. Hardwicke, of Sudbury, in this county, inoculated great numbers of patients previous to the introduction of the more modern method of Sutton, and with such success, that a fatal instance occurred as rarely as since that method has been adopted. It was the doctor's practice to make as slight an incision as possible *upon* the skin, and there lodge a thread saturated with the variolous matter. . . . . Is it not probable then that the success of the modern practice may depend more upon the method of invariably depositing the virus in or upon the skin, than on the subsequent treatment of the disease?" Also "In some of the preceding cases I have noticed the attention that was paid to the state of the variolous matter, previous to the experiment of inserting it into the arms of those who had gone through the cow-pox. This I conceived to be of the greatest importance in conducting these experiments."[3]

Jenner in only very few of his cases gave any description of the variolous inoculation; but he gave sufficient to show that, as in Ceely's cases, the inoculation was as successful as could be expected when Sutton's method was employed. We are now in a position to give Jenner an explanation of the following:—"Yet to repeat my former observation, I cannot account for the uninterrupted success, *or nearly so*, of one practitioner, and the *wretched state* [Italics my own.] of the patients under the care of another, where, in both instances, the general treatment did not differ essentially, without conceiving it to arise from the different modes of inserting the matter for the purpose of producing the disease."[1] Is it not a fair supposition that in the former case the practitioner employed the Suttonian method, and obtained "an uninterrupted success;" in the latter he did not "manage" the inoculation, and so brought his patients into a "wretched state"—*i.e.*, gave them genuine small-pox?

It is impossible to overestimate the importance of this part of the subject. It has been stated "that those persons who had been inoculated with cow-pox were protected from the infection of small-pox. This Jenner proved to demonstration, so that the fact remains outside all controversy, and is not a matter of opinion." Dr. Creighton insists that active variolous lymph was never used by Jenner, so that his vaccinated cases were really never tested. It is beyond dispute that many cow-poxed people who were inoculated with active variolous lymph, and in which the whole experiment was not "managed," readily took small-pox in its natural form.

Such then are, very briefly, some of the charges which Dr. Creighton has deliberately and circumstantially brought against Jenner and vaccination. Everyone must realize the importance of the subject in dispute. If those charges are established the credit of the medical profession is at stake. If they are false they must at once be *proved* to be so. It will not do to treat Dr. Creighton's challenge with silent contempt, simple denial, or the oft-repeated assertion that any investigation is superfluous, as the question is "outside all controversy." Be it remembered that the number of Boards of Guardians who refuse to enforce vaccination is on the increase. The Local Government Board remain inactive. Why? Let them answer Dr. Creighton's challenge: "I appeal to facts that are as well authenticated as any facts can be, and I invite the most rigid scrutiny of my use of them, or of my reasoning from them. I deprecate no criticism, but I warn the apologists of the Jennerian doctrine that any attempt to wrap themselves in a mantle of orthodoxy will be a grave dereliction of that duty which the profession owes to the public."

HEALTH RESORTS OF THE WORLD.

XXXI.—THE NEW FOREST.

By Alfred J. H. Crespi, of Wimborne.

Everyone has heard of the New Forest, and knows that the pitiless Conqueror depopulated the southern districts of Hampshire to make himself a great forest, where he and his sons could hunt, but alas! for the truth of this telling and pathetic story, a glance at the soil shows that it never could have carried a large population, so that the tale has lost nothing in the telling. Everyone, too, has heard how the Conqueror's fierce son—the Red King—on the eve of an expedition to France, rode down from Winchester, eighteen or nineteen miles, to Canterton Glen, a spot henceforth memorable in history, where, struck by an arrow in the breast, he died. Perhaps some have wondered how his death came about, whether his companion, Sir Walter Tyrrel, shot him purposely, as Walter Savage Lander tried to prove, or whether the French Baron accidentally killed him, or whether, as a dark tradition whispered, some Saxon churl, dispossessed of his hut or lands, chancing to pass by, shot the Red King, and brought his life of infamy to an end. Everyone also knows that the New Forest was fatal to three members of the Conqueror's family. There, in 1081, Richard, his second son, met his death. There died, accidentally shot by an arrow, in May, 1100, another Richard, son of Duke Robert, and there, on the 2nd of August of the same year, the Red King perished, to the grief of few.

The New Forest is that portion of Hants bounded by Southampton Water on the east and by the Avon on the west, with the sea to the south, and a line from North Charford on the west to Wade and Owerbridge on the east. In Domesday Book the New Forest was said to have seventeen tenants in chief, and seventeen under tenants, the latter corresponding to modern copy-holders; eighty-seven bordani, or cottagers—that is, people holding a bord for which they gave rent or service to the lord; sixty-six villaini, and two hundred and thirty-two serfs. The total area of the Forest is 91,000 acres, of which private owners hold 26,000 acres, while the Crown is absolute lord of 2,000, and to the remaining 63,000 it has, in common with 850 proprietors, certain ill-defined claims. About 5,000 acres are covered with ancient and well-grown timber; 10,000 with timber nearly two centuries old, and as much more with young plantations, while many thousands of acres are barren wastes and moor, usually dreary enough and swampy, though at certain seasons resplendent with flaming gorse and delicately tinted heath in full flower.

In 1670, only 5,000 acres, belonging to private individuals, had been enclosed, while in 1783, 24,797 had been appropriated or enclosed, besides 901 acres of encroachments, and 625 of Crown copyhold. As for the timber, in 1608 there were 123,927 trees fit for cutting down, and these with dotard and decayed trees, represented a total of 315,477 loads of wood. This in 1783, had been reduced by the peculation of the keepers, and the neglect of the verderers, to 20,830 loads. Deer were plentiful in the Forest for many centuries, but though large sums were paid by the Crown for hay, they also seem to have been shamefully neglected, the keepers and the poachers thinning them mercilessly; while as many as 300 died, in one Forest walk, from starvation, in the severe winter of 1787. They were finally cleared off in 1851, the Crown taking in lieu of feeding them, the right of planting 10,000 additional acres.

There are several ways of seeing the neighbourhood to advantage: the best perhaps is to take rooms at Brockenhurst, or at Lyndhurst, in the very heart of the Forest; from both places an active walker could penetrate into nearly every corner. Or a visitor could stay at Romsey, ten miles from Lyndhurst, and fourteen from Brockenhurst. This I have twice done, and in the bright, sunny and dry weather of August or September, long excursions can be made, and the Forest can be thoroughly explored. I passed September, 1875, and July, 1881, at Romsey, and found it a most charming residence, with abundant railway facilities—and its nearness to Hursley, Salisbury, and Southampton, makes

[1] "Inquiry," p. 54.

it convenient. In all these places there is no dearth of accommodation; Romsey is only sixteen miles from Salisbury, ten miles from Winchester, and ten from the famous Church of St. Cross, and, moreover, has a grand and perfect Norman Abbey of noble proportions and in magnificent preservation. Lyndhurst is the Capital of the Forest, and one of the best-situated woodland towns in England; its superb modern church, completed twenty-five years ago, has a remarkable fresco by Sir F. Leighton. Ringwood, at whose Grammar School Stillingfleet was educated, is eleven miles from Rufus's Stone, and close to Ellingham, the grave of Alicia Lisle; though more distant, it possesses some advantages, as it is easy to get to Bournemouth from it, and to Christchurch Priory Church, and not difficult to reach Swanage, Dorchester, with its ancient camp and Roman Forum, and Weymouth. Wimborne, though further off, is not inconvenient, and cheap return tickets are issued by all trains but one from May to October inclusive, to Lyndhurst Road and Brockenhurst, and the distance to the latter, twenty miles, is covered in little over half an hour. Besides its fine and unique Minster, and Chain Library, Wimborne is near some very perfect camps, the most remarkable of these are Badbury Rings, and the Castle Hill, at Cranborne. Fordingbridge, again, is not bad, while even Lymington brings some parts of the Forest close.

The visitor must depend on out-door life and long excursions for his chief pleasure; the Forest towns not being sufficiently large to satisfy the lover of busy centres of life and activity. In bad weather, rare fortunately from the beginning of May to the end of September, the district is extremely dreary, and the townsman will, I fear, utter many complaints; still, if he visits the Forest for its seclusion and woodland scenery, he can surely dispense for a time with the excitement of cities, and the din of busy populations.

As a rule, the timber in the Forest is not remarkable for its vast size, although the Boldrewood oaks are handsome, and of great bulk, so are many of the beeches near Rufus's Stone. The tree from which the arrow is said to have glanced that killed the Red King, is long dead, but its site is marked by a stone, inclosed in an ugly triangular case, bearing on its three sides the following inscription:—

"Here stood the oak tree on which an arrow, shot by Sir Walter Tyrrell, glanced and struck King William II., surnamed Rufus, on the breast, of which he instantly died, on the 2nd day of August, 1100. King William II., surnamed Rufus, being slain as before related, was laid in a cart belonging to one Purkiss, and drawn from hence to Winchester, and buried in the Cathedral Church of that City."

Anno, 1745.

"That where an event so memorable had happened might not be hereafter unknown, this stone was set up by John, Lord Delawar, who had seen the tree growing in this place."

The continuity of English life is shown by the survival of Purkiss among the local names: at Minestead, a village near Rufus's Stone, it it still seen, and a shop is kept by a descendant of the ancient possessor of the name, while at Wimborne one of the principal booksellers keeps the old family name fresh and green, and other representatives of the family could easily be pointed out.

Brockenhurst Church was mentioned in Domesday Book; it is interesting, as the following extract from the work on the Forest, published in 1862, by Mr. John R. Wise, will show; at the same time there is nothing remarkable in Brockenhurst and its Church:—"The approach to the Church remains in all its beauty. For a piece of quiet English scenery nothing can exceed it. A deep lane, its banks a garden of ferns, its hedges matted with honeysuckle, and woven together with long bryony, runs winding along a side space of green, to the lytch gate, guarded by an enormous oak with a circumference of twenty-two feet eight inches, its limbs now fast decaying, its rough bark grey with the perpetual snow of lichens, and here and there burnished with soft steaks of russet-coloured moss, whilst behind it, in the churchyard, spreads the gloom of a yew, which from the Conqueror's day to this hour has darkened the grave of generations."

The approach to the district from the Isle of Wight, and even from Bournemouth, can be conveniently made from Lymington, a quaint and rather handsome little watering place, not specially remarkable for size or situation, or for its antiquities, but prettily situated, and at one time of much greater relative importance. It is necessary, however, to be on one's guard against local traditions, and not to accept without demur exaggerated reports of departed grandeur:—"From the earliest times it evidently possessed the salt works, which so late as the beginning of the present century, made the salt trade of Lymington second only to that of Liverpool, paying, as it did, a duty of £50,000 yearly upon the produce of its Salterns. The rock salt of the north, however, has driven sea-made salt out of the market, but so long ago as 1147, Richard de Redvers, a descendent from one of the noble families of Normandy, confirmed to the Church and brethren of St. Mary, at Quarr, in the Isle of Wight, the tithe which his father Baldwin had granted to them of the Lymington Salterns. In the reign of Edward III., when it sounds quaint to modern ears to be told that Lymington contributed nearly double the number of ships and men sent by Portsmouth to that Monarch's fleet for the invasion of France, the Borough was summoned to return representatives to Parliament, but none were returned till the 27th year of Elizabeth's reign, and it is somewhat remarkable that, from 1574 to 1834, the Burrard family held forty-six mayoralties, and represented the Borough in thirty Parliaments. They appear, in fact, to have been the Sultans of Lymington. It may interest the curious to know that the modern proposal to pay Members of Parliament is simply a revival of an old custom. In earlier times, the officials of Boroughs, invited to send representatives to Westminster, frequently made a return that no one could be found willing to undertake the duty. The archives of Southampton show that Thomas Reynolds, in 1st Henry VII., received for his 'Parliament wages' from January 23rd to March 8th, £71 3s. 4d., and at Christ-church, Sir Peter Mew, about the beginning of the eighteenth century, gave a bond, the condition of which was that he would not demand any pecuniary reward of the burgesses, or put the Borough to any expense on account of his service in Parliament. In 1677, to prevent animosities and other inconveniences, it was ordered by the Mayor and Burgesses of Lymington that for the future the election of Mayor, as well as of Members of Parliament for the Borough, should be by means of different coloured 'bullets,' to be placed by each Burgess in a box for that purpose, but this order does not appear to have been acted upon, and was rescinded shortly afterwards." It will rather startle the modern Radical to learn that that excellent institution, the ballot, with its immense advantages, was actually long ago proposed and perhaps tried

at what he would regard as a very sleepy Hants. borough. Through all the vicissitudes of eight centuries the ancient Saxon Forest, the boundaries of which were extended by the pitiless Norman, has continued, in its way, to be one of the most beautiful parts of England. One landowner after another has seized upon broad belts of woodland, and large tracts of the Forest have, under one pretence or another, been cleared and cultivated; and Mr. Auberon Herbert is at this moment complaining that the resident officials are cutting down timber, and spoiling some of the loveliest parts of the little kingdom entrusted to their tender mercies. Small towns and villages have sprung up in the district, and some of the best-kept and straightest roads in the kingdom run through that part of the country. Yet, after all, for sylvan beauty, for calm repose, for solitude, for accessibility, no other tract of equal extent is so remarkable. Change there has been, but less than one would expect, and portions of the Forest remain as they were four or five centuries ago. In the New Forest the England of the Middle Age still reigns supreme.

The New Forest is said to be singularly rich in animal and vegetable life, but such claims are so generally made everywhere, that they cannot always be accepted without demur; and, as far as I can judge, it is doubtful if they have much to rest upon, as far as the New Forest is concerned. Seventeen kinds of bronzed and green ferns grow in the Forest, and seventy-two species of birds are resident in the district, while at least 230 of the 354 British species have been found in it. The insect life of the district is rich and varied, and the vegetation is, in some places, luxuriant, while in others little except gorse, heather and poor grass flourish. Taking it as a whole, the Forest is not fertile, though in the river bottoms there are patches of rich land, which, partly from natural advantages, and partly from loving care, have an air of fertility and beauty, and stand in marked contrast to other parts.

How can I describe this lovely district? Persons, ignorant that forests are not necessarily covered in all their extent with tangled old trees, fancy that, as soon as they enter the New Forest, they see on all sides vast tracts of woodland, and nothing but woodland; never was there a greater mistake. Thousands of acres, as I have said above, are covered with majestic timber; and still larger tracts with recently-planted trees, but there are also still more extensive heaths. The charm of the New Forest is, next to its extent, owing to its variety. The heather is so thick, tangled, and tall, that during the late summer, when it is literally one mass of flowers, the Forest is more attractive than the most carefully kept garden, and I know nothing equal to it for wild, unapproachable loveliness. The dry, indeed arid soil of much of the district seems, in conjunction with the bright sunshine, to suit garden flowers particularly well, and their abundance and variety are difficult to surpass elsewhere in England. So with the older woods, it is their beauty and extent that delight. The timber may not always be as large as one could wish, though hundreds of acres are densely wooded, and carry trees fully satisfying the *connoisseur*. So, with the young plantations, their extent makes them remarkable. Persons who often stroll through large woods and plantations, and are keenly alive to the beauties of woodland scenery, feel how little they have entered into the charm of a vast forest until they wander for hours in the New Forest. Nothing resembling it exists in any other part of England, and nothing like it could now be made, while under the most favourable conditions it would take two or three centuries to produce such a forest. The mildness of the climate has something to do with the luxuriance of the heather and gorse, and with the beauty of the scenery, which is equal to anything in the south of England, though falling far short of the romantic glens of Derbyshire, and the rich verdure of Brecon and Hereford. The New Forest is, on the whole, flat, though not painfully so, or rather its surface is slightly undulating, with here and there hills of low elevation, one of the prettiest of these ridges being near Romsey and Broadlands.

One of the most charming excursions from Brockenhurst is to the noble ruins of Beaulieu Abbey. For nearly three miles the road winds among trees, and it then passes for a couple more over Beaulieu Heath, and finally gradually descends for a mile into the village, and on passing through the latter, to the left the handsome house in which Lord Montagu resides is seen; while a little to the right, over the river Exe, stands the parish church, a vast building, 150 feet long; once the refectory of the ancient Abbey. The church is beautifully and reverently kept, and is remarkable for its superb pulpit, and for a covered arcaded passage in the wall leading to it. This so-called pulpit was the rostrum of the Refectory, in the days when the Abbey was in its glory, and the reader occupied it at dinner. It is said that only one or two others of such beauty and interest remain. Near to the church extend for a vast distance the ruins of one of the grandest abbeys in the land, and no ruins are more exquisitely situated. The church was only seven feet shorter than Winchester Cathedral. Well was the spot named Beaulieu.

An uneasy feeling has taken possession of the public that the Forest is in danger of being enclosed, or felled. Attempts have been made to establish absolute lordship over parts of it, and though there is little immediate danger of destructive change, no one knows what form these claims, inquiries and investigations may one day assume. The best guarantee for the preservation of the Forest is that so large a proportion of the area known as the New Forest is covered with such very young timber, that it would not be worth while to stock it up, and nothing of the kind is likely to be attempted for years. The older timber might, it is true, be cut down, and the beauty of the scenery destroyed for a century or more—assuming that the removal of the better-grown timber would not be the first step towards the cultivation of the land on which it grew. Fears for the New Forest may have been unnecessarily aroused, and there may be little prospect of destructive change, but before it is too late to assert the claim of the nation to what remains of the Forest, the opportunity must not be allowed to slip. No one could otherwise tell when the loveliest woods in the South of England, still open to the public, might be closed against visitors, and converted into private property, and no one knows when the most charming woodland scenery, the most beautiful heaths the eye could desire to rest upon, may be spoilt by the hand of man and his so-called improvements. Timber of comparatively small size is constantly being cut, both on the Crown lands and on the estates of local magnates, and as long as this thinning is not carried too far, no fault need be found, indeed it is a positive advantage to keep trees from being too thick. But in wandering through the New Forest, it has often pained me to see hundreds of trees lying in all directions. The excuse is that it is necessary to thin the timber. All I know is that, with the exception of some portions, large tracts of woodland are so sparingly covered with timber that on hot days there is hardly any shade.

Nothing is easier than to cut down a few thousand young trees and thin a wood, but it takes twenty years before those remaining grow sufficiently to fill the large spaces made in all directions. So little old timber remains in this country that we must regard with suspicion all attempts to remove fine young trees that might, one day, take the place of the forest giants whose growth had required centuries.

If what I have said of the importance of preserving the New Forest in its present state, on account of its charming scenery, historical associations, and advantages as a health resort, is not satisfactory to zealous advocates of economy, who fancy that every foot of waste land should be used to grow food for our vast and hourly-increasing population, let me remind them of a few ominous facts. Were the New Forest cleared, were the 63,000 acres remaining used for agriculture, the produce would not maintain the inhabitants of such comparatively small towns as Bath or Cheltenham. At present, half our food comes from abroad, and so rapid is the increase of population, that not even the cultivation of all the parks and forests of England would provide food for the fresh mouths we may expect in the next ten years. There is such a thing as being penny wise and pound foolish, and the destruction of ancient woods, and the cultivation of waste places, would be dearly purchased by the increased disease and suffering, and greatly decreased enjoyment of life that would result.

I have not said a word about the Forest pigs—the liveliest and most charming little creatures in the world. In September, when they are running wild, nothing is more amusing than to watch them. Thousands of little fellows, black as ebony, with sparkling eyes full of fun and mischief, are careering madly about in all directions, intent on getting food, but withal inquisitive to a degree; if you sit down quietly for a few minutes, the little fellows are attracted, and first from one quarter, then from another, you see them stealthily approaching until I have counted over twenty a few feet off, gazing with undisguised interest at the intruder. Sometimes they gain confidence, and come sufficiently near to be actually touched; but usually they pull up some little way off, and as long as the person they are watching keeps quiet they feast their eyes upon him, but if he moves they are off like a shot, at a speed so little like that of ordinary decorous farm-yard swine that one is startled. When out of reach they halt, and in due course recommence their tactics. Truly they are, as Mr. Gilpin, of "Forest Scenery" memory, well said, most intelligent animals, with little tricks and ways that to the lover of nature are an inexhaustible source of delight.

XXXII.—WILTSHIRE.

SALISBURY AND STONEHENGE.

By Alfred J. H Crespi.

In such a series of papers as that now appearing under the very comprehensive heading of Health Resorts of the World, it is better to include some districts which, in many respects, may not at first sight appear to be health resorts, but which a brief inquiry shows have substantial claims to the attention of invalids and holiday seekers. Take Wilts: what verdure! what bright invigorating sunlight! what delightful excursions! what noble timber it offers! Even in the matter of sunshine it is a pleasant change to the North Countryman, and in proof of this I may mention that a strong young man—a School Inspector—who, a few years ago, was transferred from Lancashire to Sherborne, and subsequently to Wimborne, tells me that, though his sight had always been perfect, he found the constant glare of the white roads and rocks so trying that he was, for a time, compelled to wear dark glasses. He soon got accustomed to the clearer, brighter atmosphere of the South, and now thinks nothing of a Dorset or Wilts sun. I remember, too, hearing of a Manchester man, who in late middle life, found himself for the first time at Romsey in Hants. He told his friends that the sparkling sunshine was a new revelation.

In this paper I shall describe the two great attractions of Wilts—Stonehenge and Salisbury—and because of them Wilts may well claim to be a Health Resort of the first rank. Stonehenge has been too often described to leave anything original to say, while so many conjectures have been hazarded as to its uses, antiquity, and probable origin, that the reader may reasonably hope that nothing more of that sort is to be inflicted upon him. Well, as my paper is entitled *Salisbury and Stonehenge*, something about the latter must be said, unless it is to resemble Hamlet with Hamlet's part omitted, although I shall spare the reader's patience as much as possible, and not repeat what everyone knows or thinks he knows.

New Sarum, better known at a distance as Salisbury, stands on an extensive, and on the whole, not very beautiful plain, forty miles in breadth—not in the middle of it, however, but nearer its southern border. This plain, which, contrary to the usual impression, is not perfectly flat, and which, where not wooded, is barren and unattractive, is being brought into cultivation, and is in some places sufficiently fertile, at least corn grows well. Gardens, however, flourish, and the luxuriance and abundance of its flowers are above all description.

The author of "A Hundred Days in Europe" speaks warmly and admiringly of English landscapes, their verdure, fertility and cultivation, but he was not equally struck by their trees and brilliant climate. "I recall 'Birkett Foster's Pictures of English Landscape," a beautiful poetic series of views, but hardly more poetical than the reality. How thoroughly England is *groomed!* Our New England out-of-door landscape often looks as if it had just got out of bed, and had not finished its toilet. The glowing green of everything in England strikes me: green hedges in place of our rail fences, always ugly, and our rude stone walls, which are not wanting in a certain look of fitness approaching to comeliness, and are really picturesque when lichen-coated, but poor features of landscape when compared to these universal hedges. I am disappointed in the trees so far; I have not seen one large tree as yet. Most of those I see are of very moderate dimensions, feathered all the way up their long slender trunks, with a lop-sided mop of leaves at the top, like a wig which has slipped awry." Perhaps our lively colleague had too high a standard and expected too much; for my part I was greatly disappointed by the smallness of Virginian timber, and hardly saw a single large, noble, symmetrical tree. Perhaps I was unfortunate, but so might have been Oliver Wendell Holmes.

Salisbury is eighty-two miles south-west of London, four east of Wilton, and sixteen north-west of Romsey; it stands near the confluence of the Nadder and the Wiley with the Avon. New Sarum, although generally spoken of as a very ancient city cannot claim extreme antiquity. It was commenced about 1220, and the first mayor was elected in 1227: it rapidly grew in size and importance, and remains a favourable specimen of a quiet, respectable and rather

dull old country town, with a sprinkling of handsome villas and some capital shops. In many respects Salisbury is noteworthy. Its Cathedral, world renowned for its graceful spire, towering over 400 feet in height, is a perfect specimen of unmixed Gothic. Larger Cathedrals there are, longer ones too, some too more gorgeously decorated, while others are more interesting to the antiquarian; but none more certainly fascinates the visitor. Often and often in bygone years I have walked by sunlight and by moonlight through the Cathedral meadows—a broad, luxuriant, and level expanse of splendidly timbered fields surrounding the church—and thought that nothing more beautiful could ever gladden my eyes. The Cathedral is absolutely perfect; its proportions are so just that its extraordinarily lofty spire is in harmony with the remainder of the structure, in short there is no disproportion anywhere. The exterior of the church has been recently carefully restored, and the visitor is struck by its bright, clean appearance, though after Lincoln and Ely it looks small and too much flooded with white light. Oliver Wendell Holmes was however less struck by the extreme loveliness of some of our beautiful Cathedrals than one would have expected; his words are curious to our English ears. "The old Cathedral," of Chester I think, "seemed to me particularly mouldy, and in fact too high flavoured with antiquity. I could not help comparing some of the ancient Cathedrals and Abbey Churches to so many old cheeses. They have a tough grey rind and a rich interior, which find food and lodging for numerous tenants who live and die under their shelter or their shadow—lonely servitors some of them, portly dignitaries others, humble holy ministers of religion many, I doubt not—larvæ of angels, who will get their wings by and by. It is a shame to carry the comparison so far, but it is natural enough; for Cheshire cheeses are among the first things we think of as we enter that section of the country, and this venerable Cathedral is the first that greets the eyes of great numbers of Americans." Salisbury Cathedral is a noteworthy specimen of unmixed Gothic, because, unlike most churches of the largest size, it was designed on one plan and rapidly completed before there had been time for new architectural styles to arise. As it was only thirty-eight years in construction, there is no mixture of designs—no unsightly, inharmonious juxtaposition of discordant parts. The town of Salisbury was also carefully laid out by its far seeing founder, Bishop Poore. That enlightened prelate divided the city into squares much like those of an American towns by five principal streets, running north and south, and five east and west, so that the thoroughfares remain broad and straight. In the last place Salisbury has three grand old parish churches—St. Thomas's, St. Edmund's, and St. Martin's; and is thus interesting among Cathedral towns, which often abound in small, dingy Churches, all the architectural enterprise and beauty of the City having apparently expended themselves on the Cathedral. New Sarum well repays a visit of a month or six weeks; it is an excellent railway centre and the visitor can easily get with little loss of time and at trifling expense into the heart of the New Forest, and to Wimborne, Bournemouth and Corfe Castle, as well as to many other towns.

In the immediate neighbourhood of the city there are many places of considerable interest. On the Southampton-road, a couple of miles off, stretches an extensive and beautiful park, heavily timbered, the seat of Sir Frederick Bathurst. In Clarendon Park, two miles from the high road, stood, seven or eight hundred years ago, a royal palace—some portions of which can still be seen in a deserted and tangled garden. Nothing remarkable strikes the eye in that piece of wall—thirty-four feet long and twenty high—yet it is precious to every patriotic Englishman, for there, January 25th, 1164, Thomas à Beckett and his followers signed the memorable Constitutions of Clarendon. No character has been, and is still, more keenly debated than that of Beckett, and in common fairness I must say that modern researches have thrown great additional light on the Archbishop's motives and conduct; and while his enemies have had their hatred deepened, his admirers contend that there is nothing, as far as can be ascertained, to prevent a thoughtful students defending his life and arguing that he was an enlightened and far seeing statesman and churchman, and that the usual estimate of his character is erroneous. A mile further along the road is the lovely village of Alderbury, almost hidden in trees.

Let us return to Salisbury, pass through the city and make our way towards Wilton; we can wend our steps through Bemerton, a small and not particularly pretty village, with little of the village remaining, a mile from Salisbury, and two from Wilton. At Bemerton a tiny old church arrests our attention; its door is nearly always open. In that little old church nothing striking offers itself, though on its walls are to be seen monumental tablets to Archdeacon Coxe, and Mr. Norris, men of mark in their day, the former famous as a historian, the latter as a metaphysician; both sometime rectors of the parish. You look in vain for other monuments, and, with the exception of a pretty painted window over the altar to the memory of Lord Herbert of Lea, nothing interesting is seen. Yet under that altar, at least so report says, sleeps good George Herbert, the sweet Christian poet, and the brother of the great scholar and philosopher—Lord Herbert of Cherbury. That one so gifted and holy as George Herbert reposes in a church, is enough to make it famous. Passing on to Wilton, you have, either on the right or the left, according to the road you take, Wilton House—memorable in English History—the seat of the Earl of Pembroke, son of Sidney Herbert: the latter lies in the beautiful parish church, built at his sole expense, in the Byzantine style; its is remarkable for its gorgeous ornamentation and superb Campanile; the latter is said to be a representation of the Campanile of St. Mark's at Venice. Perhaps it is bad taste, but, beautiful though that grand and costly edifice undoubtedly is, it is not as quaintly interesting in my eyes as a fine, old English, Gothic church.

Returning to Salisbury, we are ready for our long walk to Stonehenge, after seeing the old workhouse, or Diocesan Church-house as it is now, and the splendid museum founded and built by Dr. Blackmore. There are several ways of going. You can go to Ambresbury, commonly spelt Amesbury, and thence to the great stones, or along the Devizes Road—the latter as monotonous, hot and dusty, as any country road can well be; or you can wander along the Valley of the Avon for six or seven miles, then across the interminable plain for three more, unless, as commonly happens, the traveller loses his way, when he may wander about the plain for a couple of hours before reaching his destination. Assuming that the last of the three routes is selected, one has, at first, little cause to complain of the picturesqueness of the country, and the lofty and magnificent timber might even have satisfied Wendell Holmes. Two miles from the city, you see to the right a curious, but not

at first glance, a very remarkable hill—something like a stupendous barrow; and were it not so huge, it might be mistaken for the tomb of an ancient hero of more than commom renown. That hill is the site of Old Sarum, the Sorbiodunum of the Romans. It thoroughly deserves to be well explored. No architectural remains can be seen beyond a huge mass of rough masonry—probably the granary of the Castle—not a trace of the Cathedral that once stood on that lonely and almost inaccessible site, not a vestige of the Monasteries and houses of the once busy city. Yet is old Sarum deeply interesting; and the most careless can hardly help being filled with solemn thoughts as the feet press the uneven turf, growing over what was once the scene of much animation, and perhaps of great bloodshed. The silence of death reigns over the spot where Britons first, then mail-clad, iron nerved Romans, and, more recently, Saxons, lived and died. The ancient fortifications are intact, and the huge mounds and deep trenches as perfect in places as on the day when they were first constructed, and they would still be formidable obstacles to storming parties.

The Antiquities of Wilts are inexhaustible—tumuli abound: and within a few miles of Stonehenge 300 barrows can be counted, while as one skirts the eastern border of Dorset, earthworks are very numerous and stretch for miles, comprising among them the splendid camps at Castle Hill, Cranborne, and Badbury Rings, Wimborne.

The Wilts folk have quaint manners, and still shun change and distrust strangers. On both points I subjoin some curious information, for which Dr. Stevens, now of Reading, is my authority; indeed, this learned member of the profession has done much to clear up many mysteries. Forty-five years ago, when Dr. Stevens settled at St. Mary Bourne, the people generally lived in thatched houses, and had many pretensions to be considered old-fashioned. One inhabitant remembered the introduction of the first sash window in the district, and the time when the passing of a strange post-chaise through the quiet street was a sufficiently remarkable event to secure a half holiday for the school children, so cut off from all communication was the sleepy little hamlet. Corbett, in his "Rural Rides," relates a conversation he once had with a woman in the village of Tangley, which gives a vivid conception of the stay-at-home character of the people at the beginning of this century. He says: "I rode up to the garden-wicket of a cottage, and asked the woman, who had two children, and seemed to be about thirty years old, the way to Ludgarshall, which I knew could not be more than about *four miles* off. She did *not know!* A very neat, smart, and pretty woman, but she did not know the way to this rotten borough, which was, I was sure, only about four miles off! 'Well, my dear good woman,' said I, 'but you *have been* at Ludgarshall?' 'No.' 'Nor at Andover?' (six miles another way). 'No.' 'Nor at Marlborough?' (nine miles another way). 'No.' 'Pray were you born in this house?' 'Yes.' 'And how far have you ever been from this house?' 'Oh! I have been *up in the parish and over to Chute.*' That is to say, the utmost extent of her voyages had been about two-and-a-half miles."

Dr. Stevens remarks that: "The humble position of the secular clergy is shown at the time of Domesday in the mention of priests among the villeins of the manor. Bearing on this there is an entry in the Church register of the neighbouring hamlet of Woodcot: it commences with the year 1587, and contains various entries relating to the Kingsmill family, one of which refers to a 'Master of Artes' who is stated as being a servant to one of the Kingsmills. Under the Saxon laws tithes appear not to have been taken in the shape of tenths, as the tenth sheaf, but in land, every tenth strip being left for the Church by the ploughmen, if, indeed, the ploughing was not performed by the common ploughs, in return for the services rendered by the priests. In the laws of Ethelred, 978-1016, it was ordered that every man should give his churchshot and just tithe, *as the plough traverses the tenth acre.*"

In Wilts one feels that the continuity of English life is unbroken, and that the inhabitants are of the old breed still. Near the road, a little beyond Old Sarum, on the left stands an old house—one of the five or six where tradition says that the great Earl of Chatham first saw the light—and on the right is the Church of Stratford Sub Castle, noteworthy for an inscription over the doorway, "Parva sed apta Domino;" and another on the tower to the following effect, "Thomas Pitt, Esquire, Benefactor, erected Anno 1711," commemorated on the principle of not letting the right hand know what the left hand does. Beyond Stratford Sub Castle the road divides: that to the left winds through Lower Woodford and Middle Woodford to Stonehenge. Just beyond the bifurcation, walking back to Salisbury late one summer evening, the 21st of July, I was startled by hearing the clear ringing notes of a Cuckoo among the tall trees to my left. Never before or since have I heard that mysterious bird so late in the season. The road to the right takes through some magnificent beech groves, past Netton, Upper Woodford and Lake, and then straight across the plain to Stonehenge. What is Stonehenge? what does it look like? who built it? He would indeed be wise who could answer. The writer of an article on Stonehenge in the *Quarterly* for July, 1860, contended that the circle was erected between the departure of the Romans and the final conquest of the country by the Danes and the Saxons, and he gives the credit to Aurelius Ambrosius, who reigned from 464 to 508 A.D. Professor Nilssen, the Swedish antiquary, read in July, 1865, a paper before the Ethnological Society of Linden, in which he compared it to a temple of a similar description at Kiveh, in Sweden, and with Syrian and Phœnician sun temples. He considers Stonehenge to have belonged to the age when bronze was employed for weapons and implements in Western Europe, and he believes it to have been dedicated to solar worship. Sir John Lubbock, in a lecture at the Hartley Institute at Southampton, gave it as his opinion that Stonehenge and Abury belonged to the Stone Age, and this was supported by the large number of tumuli around. Dr. Thurman thought the temple was connected with solar worship. Alas! we want something certain and indisputable, and instead of that, have to be satisfied with crude and unreliable conjectures.

The following quaint passage suggests an origin ancient and musty enough to satisfy the most exacting antiquary. "In 1823," says a local handbook, "H. Brown, of Amesbury, published 'an illustration of Stonehenge and Abury,' in which he endeavoured to show that both of these monuments were antediluvian, and that the latter was formed under the direction of Adam. He describes the present dilapidated condition of Stonehenge to the operation of the general deluge;" for, he adds, "to suppose it to be the work of any people since the flood is entirely monstrous."

Let me confess that the engravings I have seen convey an imperfect, indeed, an incorrect representation of this

world-renowned pile. I have stood with one of the best finished engravings in my hand, and tried to fancy what mental or ocular obliquity induced the artist to produce such a misrepresentation, but in vain. Four circles of stones can be made out; the first and third from the outside consist of enormous blocks of sandstone, the second and fourth of smaller masses of granite: the former were perhaps found on the plain itself, the latter it is conjectured came from Devonshire, or, at any rate, from a great distance. Although a second visit deepens the impression and corrects misapprehensions there is, after all, nothing like the first look. The first time the eyes fall on Stonehenge is an epoch in one's life. "A first impression," says Oliver Wendell Holmes, "is never one to be repeated; the second look will see much that was not noticed before, but it will not reproduce the sharp lines of the *first proof*, which is always interesting, no matter what the eye or the mind fixes upon. 'I see men as trees walking.' That first experience could not be mended. When Dickens landed in Boston, he was struck with the brightness of all the objects he saw—buildings, signs, and so forth. When I landed in Liverpool, everything looked very dark, very dingy, very massive in the streets I drove through. So in London, but in a week it all seemed natural enough." Stonehenge is a heap, and not a large one, of vast blocks of stone lying in bewildering confusion, and the circles are less distinct and easy to trace than commonly supposed. Those pretty models, sold to the credulous, as representations of *Stonehenge restored* are as true to what the tourist actually sees as some of the engravings, which, to prevent the possibility of error, are marked Stonehenge. The circles are so small, that disappointment is the first impression; nevertheless, the stones, though comparatively few, are really of colossal dimensions, and their bulk only dawns upon you after you have got to know them well, and have visited them several times. The best view is from the left hand of the enormous stone close to the Heytesbury-road. Standing there, facing Stonehenge, one is unable to conceive how such stupendous masses were ever hewn or moved, and yet distinguished travellers assert that comparatively rude Asiatic races continue to move blocks of even greater size than any at Stonehenge, and for this purpose they use rollers, while they manage to raise the stones to a great height above the ground by means of inclined planes. The designers of Stonehenge must have done much the same. But what labour! Looking around other wonders catch the eye. Far and near in all direction barrows crop up in which lie ancient heroes and kings, who died so long ago that Roman coins are, it is said, never found in them—a tolerably conclusive proof that they were constructed before the arrival of the Romans.

A little north of Stonehenge extended the ancient Cursus—the uses of which can only be conjectured. It stretched a mile and a half across the plain and was probably a chariot course. At the Autumn Manœuvres, fifteen years ago, on Salisbury Plain, it was still perfect. Alas, a Vandal, in whose dense skull lurked stupid hatred of the precious relics of antiquity, has actually ploughed up a part. We are still imperfectly protected by the law against the tyranny of the opulent and powerful, and, in spite of stringent Acts of Parliament for the protection of Ancient Monuments, were a man only sufficiently wealthy and ruthless, and had he two or three titles, he might almost with impunity demolish Stonehenge, or pull down Tintern or Glastonbury. My advice to those having the opportunity is, to visit our ancient Monuments as quickly as possible. Many are gone and not a trace of them remains; some are going; and who knows when the last will disappear? Abury is almost a thing of the past. So may Stonehenge be some day. As I correct this article, which has been hidden away among my MS. for a dozen years, my eye is caught by an ominous paragraph in the *Times* uttering a lament over the impending desecration of the Cheddar Rocks, now being used as quarries. Can anyone, who has passed a summer day exploring that stupendous rift, as it looks, forget the impression made upon him? Rift it is not, only the channel left by the persistent passage of water through countless thousands, nay millions of years; but rift it nevertheless looks. It is so easy to destroy the salient outlines of such a natural marvel, and when it has lost its characteristic features, not all the king's men nor all the king's horses can ever restore it to its former majesty. The State should purchase and preserve the most remarkable remaining Ancient Monuments, natural and artificial, which ought to be treasured among the national heirlooms. Can nothing be done? Will not public opinion make itself heard? From one end of the land to the other, ancient abbeys, churches, castles, houses and walls have been swept away, and the process of destruction continues.

Well, I hope I have said enough to justify the pretensions of Salisbury to take rank among the health resorts of the world; favoured to a high degree by nature and art, full of modern comforts, with a delightful summer climate, and in the midst of noble ancient monuments, it compares favourably with many of those entirely-new seaside places to which thousands flock, but which have neither grand timber nor time-honoured associations to give them lasting and living interest.

THERAPEUTICAL NOTES.

From our Berlin Correspondent.

Methacetin, a new Antipyretic—Menthol in Asthma—Thiol a rival to Ichthyol—The use of Creolin.

To-day I have to report to you on a few new remedies. *Methacetin* is one of them. The discovery of the antipyretic properties of acetanilid (antifebrin), made by Cahn and Hopp, has proved very fruitful. It has not only added a valuable antipyretic to the list already known, but it has led to comparative researches into its chemical composition and therapeutic action. By substituting some of its chemical compounds by others, new substances, with a surer and less complicated action, have been discovered. One of the consequences of such researches was the introduction of phenacetin into therapeutics. To the same group of pharmacological products belong two other recently-introduced remedies: methacetin (examined by Mahnert, in the clinik of V. Jakesch, of Graz) and exalgin (recommended by Dujardin-Beaumetz and Bardet). Both substances are in close relation to phenacetin and antipyrin. It is at present impossible to give a verdict on these new remedies, and it remains to be seen whether they will in future attain any practical importance, and whether they have properties placing them above the antipyretics and antineuralgics usually employed, or whether they will enjoy only a theoretical interest.

The name methacetin was chosen by Mahnert for its shortness. Chemically, it would be called: acet-para-anisidin. It is derived from amido-phenol, in a similar way to phenacetin, or acet-para-phenacetin. Methacetin,

as used in Mahnert's experiments, consists of a reddish, odourless powder, of a bitter, salty taste. The powder is in the form of finest crystalline scales, soluble in cold water, more soluble in warm water and alcohol. The result of experiments made on animals was a considerable lowering of temperature, from 39° C down to 36°, and even 35°. Unfortunately, the dose by which this was effected is not indicated. This lowering of temperature was accompanied by general convulsions, showing that the whole central nervous system was affected. The fatal dose for rabbits was three grammes. The urine of the animals experimented on, was free from hæmoglobin, and possessed reducing properties. The only instance where methacetin has up to the present been tried, is in febrile diseases of children. The temperature went down slowly and gradually, and remained low for several hours. The after-effects seemed to produce frequent perspiration, and in one case collapse. Other unpleasant after-effects were wanting. The dose for children varied from three to five grains. Mahnert is quite unable to decide, from the small number of his experiments, whether the new remedy possesses considerable advantages over the familiar antipyretics.

"The Effect of Menthol in cases of Asthma" is the subject of a communication by Dr. Jores to the *Therapeutische Monatshefte*. He attended a lady who suffered from attacks of asthma and congestion to the head, which recurred every few days. By appropriate treatment the congestions were checked, but the fits of asthma grew worse than ever. Jores having heard of the favourable effects of menthol in pulmonary affections, and especially its action on the bronchial secretion, resolved to try it in this case. Crepitation and rhonchi were heard on auscultation of the lungs, before the drug was administered. After inhalation of a few drops of a 20 per cent. solution of menthol in olive oil, the attack was suddenly stopped; normal breathing was heard on auscultation; the heart's action remained unaltered; pulse remained full and strong. The patient being asked about her sensations in the head, remarked that sometimes she felt dizzy, and had sensations similar to those felt during the first stage of chloroform anæsthesia. Ever since its first administration (January 2nd, 1889), the remedy has promptly checked each asthmatic attack that the lady has had, and Dr. Jores is therefore in a position to recommend further trials of this drug in suitable cases.

Ichthyol has found a rival in Thiol, a new product of chemical synthesis, obtained by artificially sulphuretting unsaturated hydro-carbons, and charging these with ten per cent. of sulphur. Chemical and therapeutical researches prove its exact identity with ichthyol. Thiol consists of a brown fluid of the consistency of syrup; it is completely soluble in water, is totally inodorous, and has therefore a decided advantage over ichthyol. There exists also a dry thiol, which has two and a half times the strength of fluid thiol, otherwise having the same properties as the latter. Thiol is used like ichthyol in the following diseases: Acne, acute and chronic rheumatic arthritis, other rheumatic affections, contusions, decubitus, eczema, erysipelas, neuralgia, ischia. leprosy, frost-bites, prurigo, pruritus, ulcus cruris, burns, and scalds. On the initiative of Schweninger, thiol was tried at the Charité Clinic of Berlin, and Dr. Reeps reports on these trials in a very favourable light, as does also Dr. Buzzi, whose opinion is based on an even more extended clinical experience.

Dr. Reeps states that it may safely be concluded that thiol, externally applied in skin diseases, has positively the same effect as ichthyol. As their effect in these instances is identical, it may also be assumed that thiol will prove equally efficacious in other diseases where ichthyol has been employed. Reeps has taken internal doses up to two and a half grammes without discomfort or disturbance of the stomach; and he believes, therefore, that it is comparatively harmless. It has been asserted lately that this is not the case with ichthyol, but he ascribes the adverse physiological effects of ichthyol to its obnoxious taste and odour, and these are entirely eliminated in thiol. He does not consider there is any further doubt that thiol and ichthyol are two exactly identical substances, and that thiol will serve to replace ichthyol when the natural sources of the latter remedy become exhausted; even now the discovery may be recognised as a great boon, which makes us independent of nature's supply of this valuable remedy. The following are the usually prescribed formulæ:

℞ Thiol..... ʒi.
Vaselin..... ʒi.
Lanolin..... ℥i.
M. f. ungt. S. For external use.

℞ Thiol sicc. ..... gr. 2
Pulv glycyrrhizæ.... gr. 2
Glycerin tragacanth q. s.
f. pilula. S. One pill to be taken three times a day.

℞ Thiol sicc. ..... ʒi.
Zinc oxid. ..... ʒii.
Amylum ..... ʒi.
Talc ..... ℥ii.
f. pulv. S. The affected parts to be dusted with this powder.

During the last few years none of the more recent remedies has had such a rapid success as creolin, identical with a patent fluid, of which a refined preparation has been named "Liquor Antisepticus." When creolin was suddenly recommended in Germany as an unsurpassed non-poisonous disinfectant, many voices were heard which objected to the use of a remedy that was a "patent article;" but the hesitation was soon overcome when it was found that the preparation really fully deserved the claims made for it. In many hospitals, clinics, and in private practice, creolin has completely superseded the use of corrosive sublimate, carbolic acid, iodoform, etc., in antiseptic surgery. Authorities like Von Nussbaum, Von Esmarch, Professor Fröhner, Dr. Kortum, have given such favourable verdicts on creolin, that it has now become a generally used disinfectant—for instance, for sterilising instruments before operations, for irrigation of wounds after operation. Creolin is especially convenient for the disinfection of the hands. In the ophthalmic, aural, and gynæcological practice, its use has become general. For prevention of the formation of pus, and for deodorising large carcinomata, profusely discharging ulcers, creolin has proved very successful. The following are the daily formulæ in Germany:

No. 1.—Solutio Creolin (half per cent.)

℞ Creolin..... ♏x.
Aquæ dest..... ʒiv.
Sig. To be shaken before use. For the irrigation of wounds, impregnation of tampons, moistening of bandages, etc. Also for washing the genitals, and for syringing the uterus and vagina after delivery.

No. 2.—Solutio Creolin (two per cent.)

℞ Creolin..... ʒi.
Aquæ dest..... ℥vi.
Sig. To be well shaken before use. For the preparation of poultices and all dressings, for sloughing wounds, and for the disinfection of hands and instruments; also as a hæmostatic.

No. 3.—Injectio Creolin.

℞ Creolin..... ♏2 to 10
Aquæ dest.....ad ℥iv.
Sig. The injections. As a injection for gonorrhœa, leucorrhœa, and catarrh of the bladder.

No. 4.—Pulv. Creolin.

℞ Creolin..... ♏xxv. to ℥i.
Acid boracic ..... ℥iii.
Sig. Antiseptic powder. For dry bandaging; for eczema in the neck or nose.

No. 5.—Oleum Creolin.

℞ Creolin..... ♏xv.
Olei olivæ ..... ℥ii.
M. Sig. Antiseptic oil. For inunction of the hands in gynæcological practice.

No. 6.—Pilula Creolin.

℞ Creolin..... ♏xvii.
Extract et pulv. glycyrrh ..āā q. s.
Make 100 pills. Coat with collodion. Sig. Two pills to be taken night and morning.

No. 7.—Ungt. Creolin.

℞ Creolin .....♏xii.
Lanolin .... ℥ss.
M. f. ungt.

Clinical Cases.

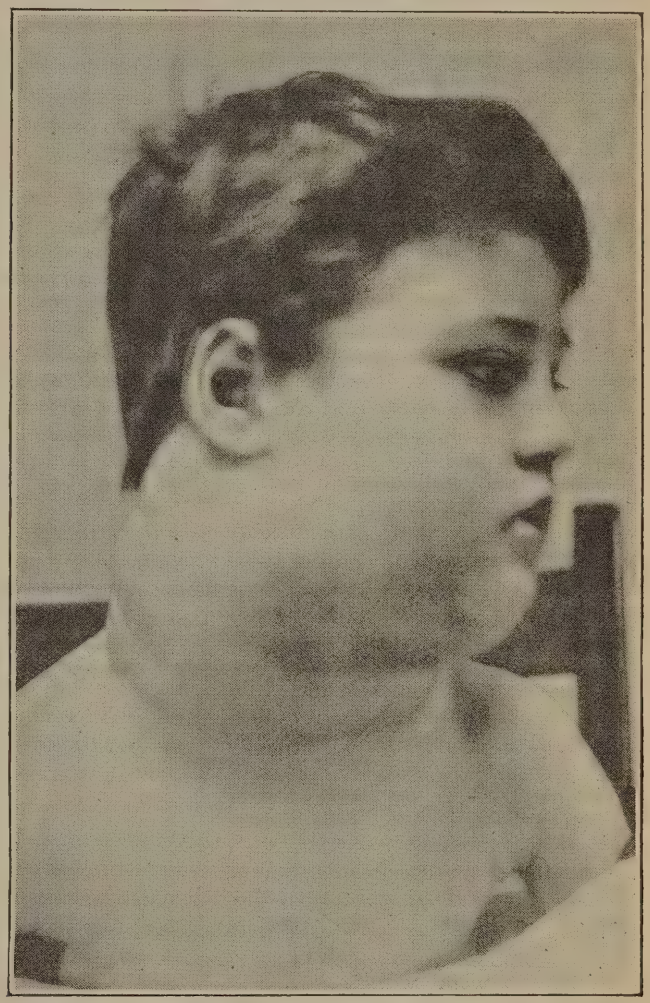
A CASE OF HODGKIN'S DISEASE.

By T. C. Railton, M.D. Lond., M.R.C.P.,
senior assistant physician to the manchester clinical hospital for women and children.

M. R——, æt. seven years, admitted into the hospital September 13th, 1888, with enlargement of the lymphatic glands of the neck. The family history appeared to be without any bearing upon the case. Her previous history was as follows:—She had two fits during dentition, measles when three years old, but no other complaint until five years old, when she had another fit. Soon after this it was observed that the glands upon the left side of the neck were somewhat swollen, and for nearly twelve months they slowly and steadily enlarged, until they reached their present size, after which they remained stationary, giving no pain, showing no signs of inflammatory action, and not affecting the general health. There was no history of any affection of pharynx, ear, eye or scalp.

Six months previous to admission, the glands upon the right side of the neck commenced to enlarge, and the increase in size proceeded with rapidity, so that when first seen they were almost of the same bulk as on the left side. On admission, she appeared to be tolerably well in health, with rosy cheeks, good appetite and strength. The glands in the neck reached from behind the ear to the clavicles, so that her face and neck appeared like a truncated cone. The glands were firm, elastic, and so connected together as to be movable *en masse*. The skin over them was of normal colour, and there was but slight tenderness on pressure. There was a small gland, the size of a marble, to be felt in each axilla, but no other superficial glands could be found, nor were any to be detected by deep palpation in the abdomen, or by percussion at the roots of the lungs. The liver in front, extended from just above the fifth rib to a little below the costal cartilages, and no more. The finger tips were slightly clubbed. The heart was perfectly normal. At the apex of the right lung there were slight rhonchi, back and front, but there was no dulness, and the rest of the lungs were normal to percussion and auscultation. There was no œdema nor other symptom of pressure. The blood showed no increase of white corpuscles. The urine was normal.

Temperature on admission, 101°.2, taken in the rectum. She remained in the hospital eleven days, after which her parents insisted upon taking her home. During her stay, the temperature varied between 100° and 101° for the first three days; for the remainder of the time it stood pretty constantly about 100, with very slight morning remissions, as a rule not more than half a degree. There was little or no change to be noted in her condition when she went out.



On going home, she felt ill and was put to bed. The tumours in the neck enlarged rapidly, especially those of the right side, and the glands in each axilla attained the size of a hen's egg. The abdomen swelled, especially on the left side, and the labia and feet became subsequently œdematous. A fortnight before death the right arm became very much swollen. She died on November 11th. The history of her progress subsequent to her removal from the hospital was derived from the relatives, as she was never seen alive after she left for home. No post-mortem examination could be obtained.

Remarks.—This case appears to be worth recording on account of the course taken in its evolution. We have the insidious enlargement of the glands on one side of the neck proceeding for a year, and followed after a period of

quiescence for about six months, by a similar increase in those of the opposite side, but differing from the former by the greater rapidity of their development, the increase in size, at all events during the time she was under observation, being accompanied by an elevation of temperature. In the course of two months this was followed by an evident generalisation of the disease, as shown by the enlargement of the axillary, intra-thoracic and abdominal glands, perhaps also of the spleen.

Reviews.

Studies in Clinical Medicine. By BYROM BRAMWELL, M.D., etc. 4to, pp. 26. Edinburgh, 1889.

"UNDER the above title" (we quote from the prospectus) "will be published on Friday, May 3rd, and every alternate Friday thereafter, during the forthcoming year . . . . . a record of some of the work done at Dr. Byrom Bramwell's Out-door Clinic in the Edinburgh Royal Infirmary. The "Studies" will consist of cases drawn from all departments of clinicial medicine. The questions put to the patient, the patient's answers, and Dr. Byrom Bramwell's remarks, will, so far as circumstances allow, be published *verbatim.*" This prospectus is accompanied by an "order form" for subscriptions, which certainly, having a regard to the illustrations and typography, is fixed at a rate that can scarcely be remunerative to the author; doubtless the publishers are able to guard their own interests. Unquestionably the publication, in its present form, has the appearance of an advertisement or trade venture, but the contents raise it indisputably above any such obnoxious representation, and suffice to secure Dr. Bramwell's reputation from the imputation of other than the most praiseworthy motives. In vindication of his mode of conducting his clinical instruction, Dr. Bramwell has the example of no less an authority than Professor Charcot. The perusal of the questions and answers here given, together with the author's clinical remarks, must afford assistance to students of medicine, giving them an insight into the intricacies and obscurities of complicated cases. The illustrative cases given in detail in the present number by Dr. Bramwell are of intra-cranial syphilis, with illustrative drawings; mitral stenosis; hemoptysis; old infantile paralysis; ulcer of the stomach, and the therapeutic value of arsenic; followed by valuable practical comments upon the difficulties, advantages, and disadvantages of out-patient practice. A volume of these "Studies in Clinical Medicine" will furnish, even to the advanced practitioner, many new views, and constitutes an available "Body of Clinical Medicine."

W. B. KESTEVEN, M.D.

The Physician as Naturalist: Addresses and Memoirs bearing on the History and Progress of Medicine chiefly during the last Hundred Years. By W. T. GAIRDNER, M.D., LL.D. Glasgow, 1889.

A REPRODUCTION of even a small portion of the literary work of so eminent a physician and author is bound to be of interest. The first essay, giving the title to the volume, was the presidential address to the British Medical Association in Glasgow last year, and is within the memory of all. Although published in the weekly journals it well bears republication in a form more adapted to careful reading and assimilation. How many members only skim the weekly journals, and of those who put aside an occasional number for leisurely perusal, how few do not allow the arrival of the new number to completely set aside the old ones? An essay like this is worthy of a better fate, and should lie on the table undisturbed by the advent of another weekly journal until it has been carefully read and digested. Dr. Gairdner's remarks on the training of the physician cannot be too often reprinted, and we offer no excuse for again directing attention to the following paragraph: "The first lesson to be learned in order to make all other lessons possible is, in my opinion, this:—to deal very largely with things and not with mere words; to realize as much as you can all your instruction by making it your own through personal observation; to suffer nothing, if it can be possibly avoided, to lie in the mind as a dead weight of vocables, oppressing the memory and dwarfing the intellect; but to bring everything into the living light of fact and of Nature, and thereby at once to assure to yourself the truth and exactness of your knowledge; while at the same time you are stamping it down upon the memory by the most sure and lasting of all technical methods."

The next essay asks the question, "Has the art of medicine advanced during the last hundred years?" After a lengthy consideration of this question he sums up as follows:—"A vast army of earnest, unprejudiced, and disciplined workers has been engaged upon all the unsolved problems connected with disease. Diagnosis and pathology have made immense strides in advance during nearly the whole of the present century. Operative surgery has achieved the most brilliant and unquestionable triumphs of any period in the long course of medical history, and this in almost every department. Hygiene and sanitation, with their reflected influence on curative medicine, have advanced by leaps and bounds; and, even in the application of strictly therapeutic methods, the changes, though not so easily stated or so palpably appealing to the judgment of public opinion (inasmuch as quackery always is and always will be more self-asserting than truth), are all in the right direction. Polypharmacy, in its old and irrational forms, is now nearly gone. Hardly anyone of intelligence supposes now-a-days that a disease is to be slain by a mere prescription or Latin formula.

A science of pharmacology, or of the uses and actions of medicines, is being built up upon a foundation that was never even possible before the present day, and which, beyond all question will render this, the least satisfactory department of the science of healing, far more secure in the future. The mere simplification in the forms of remedial agents, and the mitigation accordingly of the old, inexpressibly repulsive, and nauseous manner of prescribing them wholesale (which incurred the ridicule of Molierè two centuries ago, and yet lived on almost in our own day) represents an advance by no means devoid of importance as regards the comfort of the individual patient, and the peace of our families, and especially of our nurseries. Nor is the immense relief to human suffering by the use of anæsthetics, rightfully employed, and of narcotics and anodynes in greatly improved forms of administration, to be lost sight of, even in the most brief allusion to the modern use of drugs. All that removal, moreover, of the old traditional dogmatisms to which I have referred, has been merely a clearing of the ground, so to speak, on which a modern science of healing, not by any means forgetful of its past history, but entirely unshackled by its old errors and prejudices, is being slowly but surely built

up. And the fervid youth of the present generation, if they remain true to the spirit and not to the mere letter of the Hippocratic medicine, may well be grateful to their fathers and their grandfathers, were it for nothing else than this important and necessary process, whereby a soil has been prepared, at much cost of individual labour and sacrifice, on which they are permitted and privileged to sow the seed, and to reap more or less fruitful crops of good for humanity at large."

Of the ten other essays we propose only to mention the one in homœopathy. It is curious to note how ancient this essay, written in 1856, now appears to be, and how comparatively trivial the subject now is. Although homœopathy still lingers amongst us in name, where can we find the professor who would adhere to the extravagant dicta of its founder, or who would practise consistently in accordance with the exclusive doctrine *similia similibus?* It is not necessary in these times to overthrow the slain, but Dr. Gairdner's argument against the system in the following paragraph is worthy of repetition. "It is plain that the reduction of the homœopathic dose to an insensible and preposterous minuteness was determined by a fact which ought in reality to have determined the rejection of the system, founded, as we have seen it to be, not upon experience, but upon abstract reasoning. The first experiments, doubtless, revealed what subsequent experiments corroborated—that homœopathic remedies invariably aggravate the diseases they are intended to cure; or, as Hahnemann somewhat naïvely says, that *the artificial disease which the remedy has incited in the most suffering parts of the organism goes the length of being hurtful.* Hence the necessity of reducing the doses." We may now well ask the present professors of homœopathy if they have given up this tenet of their master: "that a homœopathic remedy always does harm when given in too large a dose, and does harm all the more in proportion as the dose is larger." The infinitesmal system having been given up, it would appear that the keystone of the structure—the *similia similibus*—must be given up therewith.

Dr. Gairdner's friends must gladly welcome this book as a reminder of the more characteristic features of his life, and the stranger will prize it as a bond of union with an author whose work cannot but give pleasure and profit to the reader. R. Shingleton Smith.

A Manual of Practical Pharmaceutical Chemistry. By George Robertson, F.C.S. London: S. F. Hodsoll.

This excellent manual will be appreciated by students who have to attend classes of practical chemistry. It is well arranged, and though the number of pages are only fifty-eight, yet the author has, by the avoidance of padding, given as much matter as is required for those subjects, a knowledge of which is demanded by the examining boards. The plan followed by the author is a very good one; the instructions are clear and easy to be followed, and if we give a sample this will be seen. We take "Morphine," Its extraction from opium is first considered, the ingredients are given, then the various steps are repeated, *e.g.*—

"Morphine (its extraction from opium) C_{17} H_{19} NO_3 H_2O.

Take of—

Opium sliced	1 ounce.
Chloride of calcium	20 grains.
Purified animal charcoal	7 grains.
Solution of ammonia, Distilled water	of each a sufficiency.

Macerate the opium for twenty-four hours with two and a half ounces of the water, and decant. Repeat the process with the same quantity of water. Subject the insoluble residue to strong pressure. Unite the liquors. Evaporate in a water bath to the bulk of one and a quarter ounces, and strain through calico. Pour in now the chloride of calcium, dissolved in two fluid drachms of distilled water, and evaporate until the solution is sufficiently concentrated to become solid on cooling. Envelope the mass in a double fold of strong calico, and subject it to powerful pressure. Triturate the squeezed cake with about half an ounce of boiling distilled water. Throw the whole upon a paper filter, wash the residue well with boiling distilled water. Filter, evaporate, solidify, and cool as before, and again press the mass. If still much coloured, repeat the process a third time. Dissolve the pressed cake in three fluid drachms of boiling distilled water, add the animal charcoal, and digest for twenty minutes; filter, wash the filter with boiling distilled water, and to the filtrate add the ammonia in slight excess. Pure crystalline morphine separates as the liquid cools. Collect this on filter paper, and wash with cold distilled water till the washings are no longer precipitated with solution of nitrate of silver, acidulated with nitric acid."

In short notes the reason for these steps are given, and then the tests are minutely detailed, after which we have an admirable description of the process of how to estimate the quantity of morphine in opium. By the student working at a bench in a laboratory these directions will be readily followed out and committed to memory, and may prove of life-long service. The book is published at a very cheap price; moreover, being interleaved, the student can himself jot down any notes he may deem fit.

Short Notices.

Aids to Ophthalmic Medicine and Surgery. By J. Hutchinson, Jun., F.R.C.S.

There is a great tendency in this age to the multiplication of books for students, short and easy roads to success in examination. On no other ground could this book have been written. For the practitioner, or for the student, really anxious to obtain a knowledge of the affections of the eye, its descriptions are too short to be of much value. Still viewed as a purely elementary work, it is well arranged, and covers a deal of ground; some of the more common diseases, those of the cornea, conjunctiva, and iris, are well described, but it is impossible to treat adequately such a subject as the refraction of the eye in a few pages of a small manual. W. T. Holmes Spicer, F.R.C.S.

Note-book for the Examination of Eye Diseases. Arranged by A. Maitland Ramsay, M.B., C.M.

This is primarily a case book for the use of students commencing the study of diseases of the eye, but it offers in addition a well arranged scheme, by which ophthalmic cases may be systematically observed and recorded. The three parts of the book are for external diseases, errors of refraction, and diseases of the fundus oculi respectively, and at the end there is a useful appendix of formulæ. Everything needed for making a complete record is contained in the book; it would have been better if more space had been allowed for errors in refraction, as these must form a large proportion of the cases. W. T. Holmes Spicer.

The Provincial Medical Journal,

JUNE, 1889.

IN the *Union Médicale*, May 2nd, there is an excellent *resumé* by M. P. RODAIT on the microbes found in discharges from the urethra. The micrococcus of NEISSER is now said to be the agent in classic blenorrhagia, but a great number of other organisms have been found in urethral discharges. What these are may be learned from the following abstract of M. RODAIT'S communication:—

M. STRAUSS has reported a case of a boy who entered the service of M. MAURIAC at the Hospital Midi, for a urethral discharge produced by masturbation. The discharge appeared two days after the act, accompanied by a sensation of burning in the urethra, with all the symptoms of blenorrhagia. The patient denied that he had ever had any relation with a woman. M. STRAUSS made four examinations at intervals on the pus, finding typical gonococci, tested by appearance and by micro-chemical reaction corresponding with preparations made from a typical case of blenorrhagia. If the veracity of the patient be accepted, and if, on the other hand, we admit the fact reported by M. STRAUSS, we must accept the view that blenorrhagia is not a malady rigorously specific, and may originate apart from contamination by an infective coitus. This is the theory of RICORD and FOURNIER, and which M. MAURIAC also admits. According to M. STRAUSS, it is probable that we have here something analogous with the pneumobacteria of FRAENKEL, and that the gonococcus of NEISSER may exist as an inoffensive host, and as a simple saprophyte in the canal of the healthy urethra, and that it may in these conditions, under the influence of irritation, invade the epithelium, and provoke the characteristic catarrh. As we have said, NEISSER'S micrococcus is the agent of classic blenorrhagia. M. LEGRAIN has found it in the thick, glazy mucus on the lips of meatus from the very commencement of the affection. The liquid is then only composed of epithelium cells of the anterior portion of the urethra, and filaments of mucine; the cocci are found on the surface of the cells. Later on, the parasite invades the subepithelial bed of the mucous membrane, and develops in the globules of pus, finally coming to the surface. Microchemically, the gonococcus is characterised by a reaction first signalised by ROUX, of Lyons. In blenorrhagia it is constant in the pus, and exists also in blenorrhagic ophthalmia, and according to VINAY, in all the ophthalmias of the newly-born, from whence this conclusion may be drawn—that the method of CREDE should be employed in all maternities. ROUX (*Province Médicale*, 1889, p. 49) has collected the cases in which the gonococcus has been met with in the different complications of blenorrhagia:

HARTELOUP and JULIAN found it in the fluid of the *Junica vaginalis;* CORNIL and BABES in the *tendenous sheaths* and *articular synovia;* PETRONE in a knee attacked with arthritis; JULIAN in the blood. The blenorrhagic pus of woman contains it, but mixed with a number of other micro-organisms, so that the application of the method of GRAM, for its discovery, becomes difficult. The medico-legal expert may have to examine cases to find out the organism of NEISSER. M. ROUX recommends the following plan:

(1) Pus is placed on two slides, but the lamellæ must not be rubbed together, otherwise the micro-organisms in the cells would be very difficult to find.

(2) The lamellæ, dried and passed through a flame, is placed face downwards in the following bath:

Aniline solution	Aniline oil ..... 3 cc.	5 cc.
	Alcohol at 50° ..... 7 cc.	
	Water .....90 cc.	

Hydro-alcoholic solution of methyl blue, 10 drops.

Leave two or three minutes in the cold. Make a first examination with this simple colouration.

(3) Wash the lamellæ in water, and bathe for two minutes in GRAM'S liquid:

Iodide of potassium	2 grammes.
Iodine.....	1 gramme.
Distilled water	100 grammes.

(4) Remove excess of iodine, and place in absolute alcohol until there is complete discoloration.

(5) Wash in water, and stir for two or three minutes in an aqueous concentrated solution of ordinary eosine.

(6) Dehydrate, clear, with essence of girofleur, and mount in balm of zylol.

These details may appear minute to those who are not familiar or acquainted with bacteriological research, but their execution does not take more than twenty to twenty-five minutes. After the action of the GRAM solution and the eosine, the preparation takes a rosy tint, the cocci are discoloured, and other microbes are coloured more clearly. In legal medicine the presence of the coccus of NEISSER may have to be established. M. ROUX'S method gives the best results for the urethral pus of man. In women we meet with the cocci, as well as a considerable number of micro-organisms. WINTER has described thirty-seven varieties found in vaginal mucus. Search for the specific coccus must be made in the clothing. LOHEN, in cultivating the coccus of NEISSER on agar-agar, believed that it liquefied, but his culture was impure. BOCKHART, KREIS, and LEGRAIN have obtained pure cultures on gelose and gelatine. Cultures have been inoculated on man and animals. Whilst BOUCHARD, LEGRAIN, and others, appear to have failed, BOCKHART, BOKI, and WELANDER, have succeeded. In the case of BOCKHART, one of general paralysis, at the autopsy there was found, besides lesion of the urethra, abscess of the kidney, which contained gonococci. The other micro-organisms met with in the urethra must be studied. The *Micrococcus diplococcus subflavus* has been described by BUNN. It was met with in vaginal mucus and lochia, vesical catarrh, abscess of the breast, healthy urethra, vaginitis, etc. The *Micrococcus citreus conglomeratus* has been recognised by BUNN and LEGRAIN in blenorrhagic pus. PRONE has described the *Micrococcus*

ochroleucus. The normal urethra contains the micro-organisms of suppuration, the *Micrococcus pyogenes aureus*, *Miorococcus pyogenes albus*. They exist also in the urethrites of scarlet fever, blenorrhagia, etc. Legrain has described a white micrococcus with foliaceous colonies, which presents itself under the form of diplococci, forming masses of ten or fifteen. The non-liquefying yellow diplococcus is not common, and may be regarded as living as a saprophyte. Some of these species have been described by Lustgarten and Mannaberg in their microbes of the normal urethra.

The *Micrococcus lacteus flaviformis* has been found in the vaginal secretions, and the *Micrococcus albicans amplus* in the vaginal mucus, and simple urethritis. Segram describes some bacilli, which he numbers 1, 2, 3, which are rarely found in urethral pus, and do not seem pathogenic. Finally he signalizes the *Spirillum roseum*, which forms red colonies, and which he twice observed in cultures of pus taken from chronic discharges. The development of blenorrhagia in man takes place in the following manner: The parasites deposited on the meatus encounter there a very thick epithelium, upon which they fertilize. Perhaps here we have an explanation of the theory of incubation, for the micrococcus only develops well in the globules of pus. The epithelial cells desquamate, allowing the parasite to penetrate into the chorion and thence into the lymphatics; then true suppuration commences, propagating itself little by little to the deep parts of the urethra, always following the course of the lymphatics. At the close of the malady, either because the soil is exhausted or the pathological modifications of the tissues render them unsuitable to the growth of the parasite, the latter returns to the superficial parts of the mucous membrane, and localizes itself on the surface. Chronic urethritis is then established. This condition has given rise to very interesting researches on the part of Legrain, who has examined the tenacious discharges which are the despair of the patient and of the physician. He has established that the micrococcus of Neisser is either wanting, or only exists in small proportions relative to the other micro-organisms. Thus, in certain individuals treated by instillations the rebellious gleet which exists encloses in the midst of epithelial *débris* an enormous quantity of microbes, which live normally on the mucous membrane. We may then ask whether the gonorrhœal micrococcus has only in these cases a secondary importance, the important *rôle* being played by saprophylic bacteria? As it is often difficult to recognize in chronic discharge the micrococcus, Legrain modifies the method of Roux. If the lamellæ placed in contact with the iodurated solution be treated by ordinary alcohol, the elements of blenorrhagic pus are discoloured in the following order: protoplasm of the globules of pus, protoplasm of the epithelial cells, nuclei of the globules of pus, nuclei of the epithelial cells, gonococci, accessory bacteria of the urethra. In allowing a drop of alcohol to flow on the lamellæ part of the preparation is discoloured, leaving all the bacteria coloured. The plate is then placed under the microscope and the point examined. A drop of alcohol is introduced, and if there be any gonococci at this point they will be found to disappear. An infective character has been attributed to blenorrhagia, and a great number of manifestations have been said to have been introduced by it. A number of old observations must be rejected, for failing cultivation we can only affirm the presence of the gonococci by the following: 1. Its form in diplococci. 2. Its presence in mass in the interior of leucocytes. 3. Decoloration by the method of Grain. The last character has only been indicated by Roux at the end of 1886. As the two first characteristics belong to other pathogenic microbes this method is essential. Now Legrain, after Ehrlich, Vogt, Petrone, Kamnerer, etc., have not been able to discover the special micro-organism, examining, according to these principles, fluids from the complications of blenorrhagia and the blood of patients suffering from this affection.

In peri-urethral abscess, etc., he has only found the *Micrococcus pyogenes aureus*, *Diplococcus subflavus*, *Pyogenes albus*, *Lacteus flaviformis*. Gerheim (*Verhumdlengen du Physik Medicin Gesellschaft zu Wursburg*, xxi.) admits that (1) blenorrhagia is an affection purely local, which can only develop on cylindrical epithelium; (2) that all the inflammatory processes which are attached to blenorrhagia are the result of secondary infection. Barnemann ("These de Copenhague," 1887) had only negative results in three cases of blenorrhagic rheumatism when he sought for the blenorrhagic organism. He also thinks that the affection results from penetration into the organism of the habitual agents of suppuration, which have availed themselves of the way opened by the gonococcus. Legrain admits, as demonstrated, that non-infective urethritis may supervene after coitus. In one case which he observed the woman had, some time previously, a peri-uterine phlegmon, and in the pus of the urethra he found the *Micrococcus aureus albus* of Passet. On the other hand, a large number of urethrites may develop in consequence of agents directly introduced into the urethra—sounds, powders, etc.; as the result of the actions of irritant substances contained in the urine, cantharides, nitrate of potash, iodide of potassium, arsenic, beer. In the first case we find in the pus the ordinary agents of suppuration, principally *Micrococcus pyogenes aureus*. Spite of antiseptic precautions, it sometimes happens that a sound retained in the urethra produces a discharge. This may be due to the irritant action of the sound, favouring the penetration into the mucous membrane of some of the microbes which normally exist on the surface of the urethra. In the second case either the substances contained in the urine are themselves pyogenic, or, by irritation, they also favour the penetration of the bacteria of suppuration. Again, there are tubercular urethritis, typhoidal urethritis, etc., so that the difficulty becomes great. The conclusion of M. Rodait, after all this display of learning, may deserve the application of a very old proverb: "Great cry, but little wool, as the man said when he sheared the pig." But we

must remember that we are expected to be posted up in bacterial literature, or we are out of the pale of medical society, and it is just as well to know the latest literature of what has been termed the "little beast"—otherwise the gonococcus of NEISSER. One conclusion only appears to us clearly to result from all the researches we have just enumerated—that is, that for blenorrhagia as well as for many other affections the discovery of the microbe, far from explaining everything, only forces us to extend the circle of our investigations."

THE Council of the British Medical Association have met the petitioners in a way that causes us a litte surprise. In future the editor of the *British Medical Journal* is to be dry-nursed; or, more technically expressed, he is to be placed under the care of a couple of assessors, to whom will be submitted each week his editorials, paragraphs, and, in fact, all the matter of the journal. This is a press censorship in an almost new form, and our surprise is that the editor himself should have suggested this plan. Whatever may have been his reasons, the matter now stands that these censors will be paid so much a week, and will have the power of rejecting or cutting out any portion of the work submitted to them. The scheme appears to us utterly impracticable, though of course it is premature to pronounce an opinion till it is tested. The advertisements will also form part of the reforms, so that the censors are not likely to have a sinecure in their office if they discharge it accurately. The memorialists made some general charges, and suggested several reforms, to which the Council have made a general defence. Before replying, we consider it would have been more judicious on the part of the Council to have asked for particulars as to the advertisements complained of, and for the reasons why the petitioners required the reviews to be signed. Specific charges should have been brought forward, and then the Council should have considered them in detail, and given their answer. It does not alter the position of affairs to appoint press-censors. The question narrows itself down into two or three points.

1. Are there any advertisements at present in the *British Medical Journal* which should not be published in a representative journal?

2. Would it be better to have the reviews signed?

3. Would it better to have the leading articles signed?

These are questions which may be considered without in any way insulting the Council, or damaging the Association. It does not meet the difficulty to say to the memorialists: "We consider you have ground for complaint; we shall be *more* careful in future; and to prevent the editor making any more mistakes, he shall have the assistance of two practitioners of repute."

It is true that the Council have made a general defence of the system adopted in regard to the reviews and leading articles, but they have not gone to the bottom of the matter. The expense involved in the new arrangement will hardly compensate the two referees, though it means expending a couple of hundred pounds belonging to the Association; whilst the benefits of the arrangement are problematical. The editor stands, or should stand, in the position of captain of a ship. He should know his work, and be trusted; he should have definite views and a policy, and should disregard, where principle is concerned, all personalities and *cliques*. He could not be expected to please every member of the Association, but in following principles of truth and justice in his editorial policy he would be sure to please the majority. Take, for instance, the articles on the College of Surgeons, which have given so much offence. Here the editor could not regard the personal equation of the eminent men who were setting at defiance the very first principles of justice. His policy was honest and clear. He sided with a principle recognised by all legislators, that representation and taxation should go together. Progress means change. The days of oligarchies are numbered, and in attacking the old-fashioned advocates of the *status in quo*, he was echoing the views of the larger number of the Association. The greatest happiness of the greater number is a principle applicable even to the very conservative profession we belong to. If the editorial backbone be removed, and he is simply to become the mouthpiece of a couple of respectable mediocrities, then the journal will sink in value, and even respectability, greatly to the advantage of its rival the *Lancet*; for, behind the scenes, there would seem to be some wire-pulling, which might possibly be attributable to a desire on the part of that very actively-managed journal not to allow the *British Medical Journal* to keep its lead.

IN medicine, certain terms or words have for years passed current, and we have been content to throw these words at our patients in explanation of their symptoms. We relieved our own consciences at the same time, because, if the truth were told, the words used only served to conceal our ignorance. A general term like "congestion," or "pelvic cellulitis," covers a multitude of conditions: it may mean anything or nothing; but though advantageous to shield ourselves, in scientific medicine we want something more. What is pelvic cellulitis? Thanks to the new school of gynæcology, and to the vigorous intellect and operative skill of TAIT, we have, during the last few years, not only had to review our knowledge of the conditions observable in the pelvic cavity, but we have been able to differentiate those conditions, which were formerly classed under one common heading. "Spasm"—a general term, very frequently applied—has lately resolved itself into gall-stones. The operation of chylocystotomy has started into life, and now spasm is being relegated into the limbo of forgotten words. Pelvic cellulitis appears likely to share the same fate; and as an index of what is taking place, not only in England, but in America, we direct attention to the views expressed by Dr. CUSHING, of Boston, on the words we have chosen as a peg to hang some remarks on.

In a paper read before the Massachusetts Medical

Society, entitled, "The Pathology and Diagnosis of so-called Pelvic Cellulitis, with Specimens of Salpingitis." Dr. Cushing tells us that it is not easy to understand what is meant by pelvic cellulitis, but the general view is something like the following: The course of the cellular tissue in the pelvis is pretty well known. Areolar tissue, loosely connected, runs between the folds of the ala vespertilionis up along the psoas muscle, inwards round the cervix, and between it and the bladder, outwards to the inguinal ring, and downward between the rectum and vagina. Now this is precisely the course taken by the pelvic collections of pus in seeking for an outlet; and when, on examination of a patient, a mass is found laterally and posteriorly to the uterus, nothing is more natural than to suppose that the hard mass is in the thickness of the broad ligament, and thus entirely outside of the abdominal cavity, below the peritoneum. If the mass enlarges, it would be held that the peritoneum lining the *cul de sac* of Douglas is lifted up, still leaving the effusion of lymph extra-peritoneal. If after death the ovaries and tubes are found diseased, it was urged that they were bad cases, and therefore fatal. If the pelvic peritoneum be inflamed, it is held to be by extension of the disease from its point of origin, between the folds of the broad ligament, around the blood-vessels and lymphatics. This Dr. Cushing understands as the doctrine of cellulitis or parametritis; but he asserts, it is fascinating, but false, except, perhaps, in certain puerperal cases, where a rent, extending at the side of the cervix right into the areolar tissue, may become septic, like any other wound. Dr. Cushing asks: "How shall we explain the symptoms? If the mass or masses which we feel are not in the broad ligament, where are they? If not effusions in the areolar or cellular tissue, what are they?" He answers his questions:

"In answering, I will premise that I am well aware that, in one sense, the tubes and ovaries are between the folds of the broad ligament; but when speaking here of the broad ligament, I mean that part of it which comes up to the limit of the side of the tube, or to the hilum of the ovary—regarding these organs as practically in the general cavity of the abdomen, like the fundus of the uterus itself. I answer, then, that the mass as felt is in the pouch of Douglas, behind the broad ligament, or laterally at the side of the fundus uteri, or even sometimes on one side posterior and on one side anterior to the latter. What is the mass? It is a distended tube, or tube and ovary, which may or may not be imbedded in a mass of lymph more or less recent. In bad cases there may be pockets of serum or of pus outside the tubes, but yet within the cavity of the peritoneum, above the latter, and roofed in by coils of intestine matted together and lined with lymph, which may form a strong and smooth membrane, a sort of sac for the abscess. If the areolar tissue is entered, it is secondarily while the abscess is finding its way out along the lines above described. The diagnosis is to be made between this condition, with its various subdivisions, and the tumours proper and cysts which are found in the same locality. These comprise—distended tube and its complications: hydrosalpinx; hæmatosalpinx; pyosalpinx; tubercular salpingitis; tubal pregnancy; abscess between tube and ovary surrounded by sac; serous collection in pouch of Douglas adjacent to tube, and roofed in by adherent intestines; pus pockets in the same locality as the last, but usually more thoroughly enclosed by a wall of lymph. Tumours or other possible conditions: parovarian simple cyst; parovarian papillomata; small cystic tumour of ovary; small dermoid cyst; fibroid tumours of uterus; fæcal collections; hæmatocele (intraperitoneal); cellulitis proper: periproctitis and perityphlitis; psoas abscess, descending; abscess around vermiform appendix, descending; infected wound of cervix and vagina. Inflammation of hæmatocele (extraperitoneal), or of tubal pregnancy (after rupture between the folds of the broad ligament). The differential diagnosis of the above affections is often difficult, and sometimes impossible, without an exploratory incision. Very frequently two or more of them are combined—*e.g.*, the chief cause of suffering in a case of fibroid (myoma) of the uterus may be, and often is, a complication with pyosalpinx. So also a tube in a state of moderate catarrhal salpingitis may, when nearly healed, become the abode of a tubal pregnancy, and this in turn may, by rupture, lead to a pelvic hæmatocele, and to severe attacks of pelvic peritonitis."

Dr. Cushing enters fully into the diagnostics of these varied conditions, contending that his view explains the real nature of pelvic cellulitis. The part played by gonorrhœa in the production of tubal disease is well emphasized in this paper. He says: "The immense importance of gonorrhœal infection in causing tubal disease is becoming more and more appreciated, both by the profession and the public, and the erring husband who hereafter infects his wife will receive the execration he deserves. An important duty rests on the members of the profession in duly impressing on men the danger of infecting their wives even after they themselves seem to be cured."

Dr. Cushing's paper should be read in full, as well as the excellent discussion which took place upon it. As Dr. Sinclair truly said: "The subject is intensely broad. I do not know of another in the whole domain of gynæcology that is wider and more interesting." The paper and discussion will be found in full in the *Journal of the American Medical Association*, April 20th, 1889.

The *New York Medical Journal* of April 27th, in an article on "Orthopædic Surgery in England and the United States," passes some severe but unsupported strictures on the barren state of English orthopædic surgery. We are gravely told with charming frankness that we are just thirty-five years behind the United States. This may surprise those of our readers who pay careful attention to current literature, and who are apt to believe that the so-called American school are only united in disagreeing the one with the other. We are willing to admit the

laboured submission that there is in America a greater tendency to the specialisation of orthopædics than is manifested in this country; but the corollary that in consequence a greater progress has resulted is absolutely devoid of justification. English surgeons believe, and with much reason, that there is nothing calling for special training in orthopædic surgery, and a close study of the American standard essays does not in the least tend to lessen this conclusion. The author of the article in the *New York Medical Journal*, however, is badly infected with what Mr. HERBERT SPENCER would term the "bias of patriotism," and can see no merit in any joint apparatus which fails in allegiance to what is erroneously termed the American method of extension. We say *erroneously*, for the very simple reason that in the use of traction for joint diseases Sir BENJAMIN BRODIE preceded by some years Dr. H. G. DAVIS, of New York, to whom American surgeons ascribe the merit of discovery. In the fifth edition of his work on "Joints," published in 1850, BRODIE says: "In some cases I have endeavoured to prevent it (dislocation of head of femur) by the application of a moderate but constant extending force." He adds: "It may be worth while to give this mode of treatment a further trial." True it is that this careful and reliable clinical observer found occasion, after more extended trial, to discontinue its use, but what merit there exists in its introduction must not be carried across the Atlantic. At a much earlier date than this, JAMES, of Exeter, first demonstrated the value of traction when employed in certain fractures. Clearly, therefore, the American claim to the so-called American method requires precisely that revision with which it is best to meet an error of fact.

The article, however, has been inspired by a pamphlet written by Mr. THOMAS, of Liverpool, and entitled, "An Argument with the Censor of St. Luke's." The precise circumstances which called forth the polemic we will refer to in a future number. Suffice it to say, that we fully sympathise with Mr. THOMAS'S endeavour to cast discredit upon a species of intolerance which would not for one moment be permitted in this country, and which culminated in the enforced resignation of Dr. JOHN RIDLON from the surgeoncy of St. LUKE'S, because Dr. SHAFFER did not approve of any deviation from what he was pleased to misname the *American* method.

The writer of the article we are discussing is evidently very ignorant of Mr. THOMAS'S splint and of Mr. THOMAS'S principles. A very few instances of misrepresentation will suffice. The late Dr. HUTCHINSON, of Brooklyn, is referred to as if he preceded Mr. THOMAS in the use of patten and axillary crutches. It is needless to remind our readers that this is hopelessly erroneous. But when the writer further points a resemblance between the THOMAS and HUTCHINSON methods—although the latter advocated no splint, but merely allowed the limb to become a pendant—serious criticism becomes very difficult. In proof that the writer has never seen a THOMAS'S hip-splint properly applied, we need only draw attention to his description of the upright as "extending to the lower end of the thigh bone." There is not an intelligent student of three years' standing capable of so elementary a blunder. It is stated Mr. THOMAS claims that his hip-splint absolutely immobilizes the joint. We have his work before us, wherein he distinctly states that he regrets his inability to attain perfect rest for the joint. Absolute immobility he cannot get, but he secures as much as he can, and more than is to be obtained by using any other splint. When he is charged with too mechanical a view of the subject, a very scant knowledge of his principles is evinced. Over and over again he has asserted that he lays stress, not upon a mere apparatus, but upon those principles which give to any splint its power for good or evil.

THOMAS differs from SHAFFER on many points, but the salient differences are concerning rest and extension. The one looks upon the terms as almost convertible, the other as dangerously antagonistic. SHAFFER thinks that by pulling upon the hip-joint the articular surfaces are separated, and inter-articular pressure relieved. THOMAS teaches that in the early stages of the disease, the greater the pull the greater the articular pressure; and a reference to the construction of the joint will at once demonstrate that the only way to relieve inter-articular pressure by extension, is to pull from its environment the lower segment of the acetabulum. The posterior hip splint is charged with making a fulcrum of the inflamed joint surfaces. If the writer could explain to us any method of reducing hip deformity, without using the joint as a fulcrum, he could indeed establish, with great show of reason, a peculiarly great American invention. In this country we are ignorant of any such method, and we are sufficiently heretical to believe that to reduce joint deformity it is absolutely essential to increase the inflammatory condition.

Mr. THOMAS'S pamphlet requires an answer, but the critic should at least possess an elementary acquaintance with the principles it advocates. It is not enough to give us vague and vain-glorious generalities about our national lassitude, nor to assume a superiority which is scarcely modest, and certainly not just. Surely a scientific question cannot be adequately or impartially discussed if the subject be made one of patriotism, and be thus reduced to an atmosphere redolent of childhood and of school. Nor is it quite frank to keep carefully in the background a species of hospital tyranny, which we feel sure must be abhorred by mostly all the many excellent American surgeons. Above all, no surgeon, however able, should for one moment allow himself to pose as the know-all and the end-all of surgical knowledge. There is no reason why freedom of opinion and action should stop short at surgery.

BAUER, who has done more for orthopædics in America than almost any surgeon, and who has been one of the pioneers of extension, writes thus in favour of THOMAS'S splint:—"All contrivances introduced by DAVIES, SAYRE, TAYLOR, ANDREWS, BARWELL, and *by us*, have been laid aside as worthless and directly obnoxious, because they procure extension, which is needless, and fail in

immobilizing the joint, which is indispensable." Such tribute, coming as it does from so distinguished a source, should compensate Mr. Thomas for any misrepresentation he may have to endure. We are not only willing but delighted to admit the earnest efforts which American surgeons are making to advance orthopædics, but with such names as Macewin, Ogston, Parker, Thomas, Noble Smith, Macnamara, and others equally prominent, we can scarcely rest content under the stigma of antiquity.

Annotations.

"Forsan et hæc olim meminisse juvabit."

APOSTOLI'S METHOD IN THE TREATMENT OF UTERINE DISEASE.

At a meeting of the New York Academy of Medicine (*New York Medical Journal*), Dr. Jacobi gave an interesting *resumé* of what was known of the results of this method. Dr. Jacobi said that exact stastistics were rather difficult to find, considering the wide-spread reputation of the method. Carlet's thesis contained an account of ninety-four cases. In five of these the tumours had been very large, rising nearly to the ziphoid cartilage, and had been treated partly by galvano puncture. In one this treatment had not lasted long, and no result had been reached. In four, after from a month to a year of treatment, the relief obtained had been considerable as regards symptoms, and the tumour in one case had diminished three fingers' breadth, but much less in the three others. Eighty-nine cases had been treated exclusively by intra-uterine cauterization and positive and negative poles. In two of these pregnancy had been unrecognised, and abortion had resulted; in one there was subinvolution, and in one incipient cancer. Four cases of sub-peritoneal fibroid had been treated; in the first of these relief had been obtained after a month, and the length of the uterine cavity had been reduced from thirteen to twelve centimetres; in the second the tumour had risen above the umbilicus. Single cauterizations had been followed by an abscess, which had been open through the abdominal wall, but also by some diminution in the size of the tumour. In the third the tumour had reached nearly to the Ziphoid cartilage, and the cavity of the uterus had measured twenty-one centimetres. Fifty-two cauterizations, given during a year and a half, had been followed by an entire relief of symptoms, and a reduction of the cavity to twelve centimetres. In the fourth the tumour had risen above the umbilicus; the symptoms of the patient had been entirely relieved, but without diminution in the size of the tumour. In four cases of interstitial fibroid, treatment of short duration had given negative results in three, but in the fourth the length of the uterine cavity had been reduced from fourteen to twelve and a half centimetres. The seventy-seven remaining, afforded from their description no adequate proof of the existence of a tumour. The descriptions given correspond rather to chronic metritis. In forty-seven of these cases entire relief of symptoms and some reduction in the depth of the uterine cavity had been obtained. In thirty cases the results of treatment had been negative, but in several instances a pre-existing perimetritis had been seriously aggravated by the intra-uterine cauterizations. The net result went to show that the Apostoli method was valuable in the treatment of chronic metritis, or for the relief of the symptoms caused by small fibroids. It seemed in a few cases to have occasioned a certain diminution in the size of large tumours, but beyond this Apostoli had published no positive results.

Dr. Keith, of London, spoke enthusiastically of the method, but gave no statistics, only stating that he had made twelve hundred applications to one hundred patients, a proportion to each patient which was scarcely large enough to judge of the value of the method by. Engelmann, of St. Louis, in an elaborate paper on the theory of the method, did not give the history of a single case. Martin, of Chicago, had stated that he had seen tumours from the size of an apple to that of a cocoa-nut disappear under treatment, but gave no details. Everett, in the *New York Medical Journal* for April 18th, 1885, had given a list of seventeen cases of undoubted tumours treated by the intra-uterine method. In three of these, polypoid tumours had been extruded after external faradization of the abdomen. In two cases submucous fibroids had been said to be cured after intra-uterine faradization lasting in one case nearly four weeks and in the other three months. In three cases pedunculated tumours had come down to the os externum under the influence of faradization and had then been removed. In six cases galvano-puncture had been employed. In two of these patients recovery had afterward been obtained by laparotomy and excision, in one by the extrusion of an interstitial fibroid into the uterine cavity, in two life had been terminated by cancer, and in two by tuberculosis; finally, in one there had been a dangerous collapse, but the patient had recovered and shrinking of the tumour had followed. Freeman, using Cutter's method of galvano-puncture through the vagina and abdomen simultaneously, had met with four deaths in a series of fifty cases, and had reported three successful cases. Webb, an enthusiastic observer in Apostoli's clinic, had related the history of three remarkable cases of sub-peritoneal fibroids. The first had filled the abdomen up to the sternum; after three galvano-punctures and thirty-eight intra-uterine negative cauterizations during a period of eighteen months, the upper border of the tumour had come only to within a hand's breadth of the sternum. In the second case the tumour had risen two inches above the umbilicus. Fifteen galvano-punctures during a period of eleven months had caused it to fall to a point two inches below the umbilicus. In the third case metrorrhagia had entirely ceased after the fourth puncture. Dr. W. H. Baker had been quoted by Dr. Buckmaster as having said that in one case he had seen a tumour entirely disappear

after treatment by galvano-puncture, and in twelve cases shrink to from a third to a half of its former size. Dr. Massey, in his recent volume on the use of electricity in pelvic diseases, had reported two cases of his own in which subperitoneal fibroids had been reduced to two thirds of their original size with full relief of symptoms, one case in which a submucous mural fibroid was extruded after thirty-eight galvano-chemical cauterizations, one case in which a small submucous fibroid was cured after thirteen applications, and four cases in which intramural fibroids had been much reduced in size. He quoted Holland as having caused sloughing and complete enucleation of a tumour reaching to the umbilicus, after nine cauterizations given during one month.

THE LATEST RESULTS OF THE PASTEUR INSTITUTE.

WE shall continue to chronicle each month the deaths. (See p. 294, May, 1889.)

CASE VIII.—Arenes, æt. fifty, bitten at Solez, Spain, 26th January, 1889. Treated at the Institute from January 29th to February 15th. Died at Hotel Dieu, February 22nd. Period of incubation eighteen days. Was the evolution of the malady hastened by the intensive treatment? This is an hypothesis certainly as worthy of attention as any of the hypotheses suggested by M. Pasteur.

On February 4th, 1889, an Austrian, an Italian, and four Egyptians were bitten by a dog supposed to be rabid. The Italian was sent to the Naples Pasteur Institute, and was treated according to the method. The child died on April 5th of hydrophobia. The three others are in perfect health. Of course the child that died was the worst bitten? No! The others were bitten on face, arms, and thigh; the child that died was bitten on the right arm.

MEDICAL MATTERS IN HOMER.

MEDICAL men at one period were distinguished by their attachment to the classics; now all this is changed, no doubt due to the reaction against the old system of education. We cannot here go over the old arguments as to the relative value of the old and new systems, but for the benefit of those who still have a regard for the classics, we give an abstract of an able paper by Dr. Kums, on Medical Matters as contained in the pages of Homer (*Progrès Medical*, May 4th). Kums takes us back to the heroic age, and to the grand old poem which is ever fresh, though many great singers have sang to us since. From the poems of Homer we learn that there were army surgeons with the Greeks—the two sons of Æsculapius, Machaon and Podalyonus, who were distinguished practitioners. Machaon was probably an ancester of the MacMahons, who afterwards settled in Ireland, and of whom many were fighters and surgeons. This may be said to be a stretch of imagination, but looking at the names, the derivation is simple. Machaon was as fond of giving a blow as of healing a wound—a trait which his descendants still possess. Achilles and Patroclus appear to have possessed medicines; but medicine for internal remedies was not much used. For wounds by arms the Greeks were well prepared. They sucked the wounds to make them aseptic, and then poured in healing balms. The balm which Archilles possessed served as a medicament, and also prevented putrifaction in the body. Sulphur was employed for purification. The beautiful Helen possessed an elixir, brought from Egypt, a few drops of which mixed with drink dispelled all pain. The philter of Circe was celebrated, as well as the fruit of the Lotophages, which resembled opium in its action. Wine enjoyed a great *role*. When Nestor brought the wounded Machaon into his tent, he made him drink. Wine took the place of the anæsthetics we use in modern times. Sleep and dreams are treated of by Homer. Dr. Kums' interesting study is published in the *Annales et Bulletins de la Societie de Medicine d'Amiens*.

ARMY AND NAVY MEDICAL OFFICERS.

SIR GARNET WOLSELEY must have had the medical officers of the army and navy in his mind when he wrote the following in the *Fortnightly Review*:—"How many soldiers and sailors have died nobly, whose very names have been forgotten because they have found no poet, no historian, to record their noble actions! How many have survived to find their achievements attributed to others, or at least to obtain neither reward nor recognition! This is a reflection that must make many blush whose deeds—perhaps less commendable—have been trumpeted in despatches, and loaded with honours and rewards. Many indeed, have been the brave men who, after great services to the State, have died in peace unknown to fame! Their pride and modesty combined to prevent those services being recognised by the country they loved and served so well."

THE COMMISSION ON VACCINATION.

THE Commission on Vaccination may clear the atmosphere a little. It all depends on the witnesses. The following are the points to which the attention of the Commission will be directed: (1) The effect of vaccination in reducing the prevalence of and mortality from small-pox; (2) what means other than vaccination can be used for diminishing the prevalence of small-pox, and how far such means can be relied on in place of vaccination; (3) the objections made to vaccination on the ground of injurious effects alleged to result therefrom, and the nature and extent of any injurious effects which do, in fact, result; (4) whether any, and, if so, what means should be adopted for preventing or lessening the ill-effects, if any, resulting from vaccination, and whether, and if so, by what means vaccination, with animal vaccine, should be further facilitated as a part of public vaccination; (5) whether any alterations should be made in the arrangements and proceedings for securing the performance of vaccination, and in particular in the provisions of the Vaccination Acts with respect to repeated prosecutions for non-compliance with the law.

INSANITY AS THE RESULT OF GYNÆCOLOGICAL OPERATIONS.

Dr. T. Galliard Thomas was mistaken in asserting that "there was no literature in this respect previous to 1887," and he can hardly be credited with being the first to describe a new form of insanity after gynæcological operations. It is quite true, as Dr. Shelley points out in the *Medical News*, Philadelphia, April 27th, that Mr. Lawson Tait in 1884, in a lecture at the Jefferson Medical College, published in *Medical News*, September 27th, 1884, fully described this condition. He said in 1884: "Removal of the uterine appendages. . . . After the operation. . . . So far we have not had any trouble, except *from one thing, and this a distressing one.* It occurs after all sorts of abdominal operations, after exploratory incisions, after the removal of one ovary for cystoma, after the removal of both ovaries for cystoma, and after hysterectomy. I refer *to the occurrence of acute melancholia.* All the cases of mental alienation that I have seen following these operations, are seven in number, and all have taken the direction of this most unfavourable form of insanity—acute melancholia. I cannot say that any one of them is likely to recover. I do not know that this is a necessary result in a certain number of cases. I have performed abdominal section some 960 times, and in this number I have met with seven cases of acute melancholia. Of course, a good many of these cases died, especially in the earlier years of my practice. We may state that acute melancholia occurs in about one per cent. of those submitted to abdominal section. I do not know that anything like this follows other surgical operations. This is the only after-result of an objectionable character with which I am acquainted."

RABIES IN FRANCE DURING 1888.

"There is no country in the world," says the editor of the *Gaxette Hebdomadaire des Sciences Medicales de Bordeaux*, "which has more dog-bitten patients than France, and no country where, spite of anti-rabic inoculations, there are more deaths to deplore, due to rabies." This remark was called forth by a paper by Dr. Drouineau in the *Revue Sanitaire de la Province*, on the increase of rabies in France. Dr. Drouineau insists on the stringent application of the French Dog Laws found so effectual in parts of France. He concludes a very able paper with the following paragraph: "Je suis convaincu que M. Pasteur ne se croirait pas atteint dans sa réputation scientifique si les préfets, vigoureusement relancés par l'administration supérieure le privaient d'ici quelques années de son nombreux contingent d'enragés et si le Gouvernement en débarrassait une bonne fois son Institut. Il en serait quitte pour étudier d'autres virus ou d'autres microbes, et aurait encore la part belle. Mais pour nous, quel ennui de moins, et pour l'administration quel succès de faire échec à M. Pasteur! Hélas! pour tout cela, il faut aimer les hommes plus que les chiens et vouloir faire *effectivement* de l'hygiène publique."

FATHER DAMIEN.

Father Damien, whose heroic death among the lepers from that dreadful disease has recently taken place, was born on January 3rd, 1841, near Louvain, in Belgium, where his brother (a priest) still lives. His mother, a deeply religious woman, died about two years ago, and his father twelve years before. On his nineteenth birthday his father took him to see his brother, who was preparing for the priesthood, and left him there while he went into the town to dine. When he came back, young Joseph told him he did not wish to return home any more, and that as he had wished to become a priest so long, it would be better to miss the pain of farewell. His father consented unwillingly, but was obliged to hurry home. In 1873 he went to work among the lepers, his heart having been stirred by the report of the sufferings and disease of these poor unfortunates. No one can tell the good he has done. When he arrived at the settlement, it was a miserable place; the houses were wretched, undrained, and unventilated; the people ill-fed, ill-clothed, and worse washed. The water supply was very bad. The sufferers were desperate, and often led vicious and lawless lives. Now all these things are changed. Father Damien built a church, Government built neat cottages, and the water is brought in pipes from a never-failing water supply. Father Damien's house adjoined the church, and his comrade, Father Conrad, a man of considerable refinement and of warm affections, lives on the ground floor. Two laymen, Brother James and Brother Joseph, assisted him in the teaching, visiting, and other ways; and they were often in communication with Kalampapa, where live and work Father Mendolen and three Franciscan sisters. Father Damien always expected that sooner or later he would become a leper, though he could never tell exactly how he caught it; but it was not likely he could escape when he was constantly living in a polluted atmosphere, dressing the sufferers' bodies, visiting their death-beds, and even digging their graves. Many entreating letters were written him, to leave the place, now that he had done so much good; but all these he refused, preferring to die among the people for whom he had done so much.

THE ROYAL COLLEGE OF SURGEONS AND ITS MEMBERS.

The branches of the British Medical Association are almost unanimous in supporting the demands of the members for reform. The following stereotyped resolutions have been passed by a number of the branches:—

1. "That this meeting sympathises with the desire of the Royal College of Surgeons of England to take part in the management of the affairs of the College."

2. "That this meeting strongly approves of the reform of the Royal College of Surgeons of England."

These resolutions should not remain dead letters: they should be sent in each district to the respective Members of Parliament.

THE MEDICAL SICKNESS AND BENEFIT SOCIETY.

MR. NEISON, the well-known actuary, has just completed his analyses of the working of the above society during the last five years; and from his report, it appears that not only is the society in a sound position, but that it has a surplus of £6,000, which can be divided amongst the members, or applied in some way for the general benefit of the society. We have to congratulate the Management Committee upon the successful way they have piloted the society through the first five years of its existence. Copies of the report may be obtained from the Secretary, Mr. J. C. Radley, 26, Wynn-road, Brixton, London.

GENERAL PRACTITIONERS AND MEDICAL CHARITIES.

WE congratulate Mr. W. Moore, Stourport, upon the able manner in which he brought this subject before the members of the Worcestershire, Herefordshire, and Gloucestershire Branches of the British Medical Association, at the conjoint meeting held at Worcester on May 6th. It is quite true, as Mr. Moore suggested, that no apology was needed for bringing the subject up for discussion at the branch meeting of the British Medical Association. Mr. Moore could not say anything very new on this subject: the question is beyond the stage of discussion. The evils are admitted, not only by the profession, but by political economists. Pauperisation on a large scale is going on, and the hospitals are the chief agents at fault. It is for the bulk of the profession to agitate, and if they want any material to base their arguments upon, they have only to turn to the files of the *Provincial Medical Journal.*

DEGREES FOR LONDON STUDENTS.

THE Blue Book containing the evidence given before the Royal Commission on the proposed University for London will shortly be published. There is a growing desire on the part of the bulk of the profession to possess the title of M.D. The Scotch have hitherto enjoyed great advantages in this respect. The English, with their M.R.C.S. and L.R.C.P. qualifications, have been placed in an unjust position. It is an advantage to have a University diploma. Unfortunately, the corporations which grant the licences are very powerful, and the leaders in medicine are not only highly conservative, but obstructive. We have only reached the beginning of the struggle, but we trust it will be continued, and that London students will in due time be placed on a footing with their Scotch *confrères.*

SYRINGOMALIA.

THIS is a disease in which the cord contains cavities of abnormal size and distribution. There is a very good summary in the *Medical News*, May 4th, on the literature of the subject, from which we learn that as an anatomical curiosity it has been known for two centuries; as a type of disease it has only been clearly recognised during the last ten or twelve years. In Germany and France somewhat numerous contributions to its literature have been made during recent years; English and American medical writers have supplied but few. Gowers' "Treatise on Nervous Diseases," however, contains a valuable discussion on the pathology of the affection; and Starr, in May, 1888, published in the *American Journal of the Medical Sciences* an interesting summary of its literature, pathology, and symptomatology. Debove and Déjerine (*Gaz. Hebd.*, March 1st and 8th, 1889) have furnished two of the most instructive recent papers in the form of carefully detailed records of two patients who were exhibited before one of the French medical societies. The rapidity with which, in this age of medical enterprise, the literature of a subject grows is shown by the fact that five years ago Fürstner's collection of four cases, with autopsies, was quoted as a most valuable contribution to the subject; while in 1887, Bäumler had succeeded in collecting one hundred observations—sixty-six with autopsies and clinical histories, twenty-five purely anatomical observations and ten purely clinical cases.

THE BRANTHWAITE HOME.

WE have on several occasions alluded to the value of licensed houses under the Inebriate Acts. Managed by medical practitioners, who have a vocation for this class of work, institutions of this kind are powerful for good. The establishment at Halesowen, Worcestershire, known as "Colman Hill House," has for years been engaged in this good work, and under the management of Drs. Kerr and Dene, it has obtained a wide reputation. The house has lately been transferred to another medical man, who has for years been engaged in similar work. It is now carried on under the management of Mr. H. Branthwaite, F.R.C.S. Edin., Mrs. H. Branthwaite, and Miss E. F. Branthwaite. We have every reason to expect that under the personal influence of this family the institution will sustain its prestige.

THE NETLEY SCHOOL.

IT seems almost incredible that there should be any question at the present day on the advantages of training all medical military cadets at Netley, or that we should have to defend a system which has worked for so long and with such advantage to the British army. Pecuniary considerations, when the medical service is concerned, would appear to outweigh all others. The Indian medical officers who have uudergone a course of training at Netley, have gone out fully equipped, and India, thought it may gain pecuniarily, will, we fear, suffer in other respects if the training at Netley be abolished. As far as we can gather, some of the Indian medical officers are in favour of the latter step, but we have not seen any arguments brought forward in support of this reactionary policy. It would be unmilitary to take a plebiscite of the medical officers in India on the question, but we are inclined to think that if such could be done, the vast majority would say: "Spare Netley to us!"

THE GERMICIDAL TREATMENT OF DISEASE.

We have laid down as an axiom that *bacteriology should not be the master but the handmaiden of medicine*. Unfortunately, as with all medical fashions, this interesting study has developed into a kind of mania, and the search for micro-organisms has for a time so absorbed all other aspects of disease problems, that clinical medicine and therapeutics have been pushed into the background. When Virchow started his cellular pathology, the cell gave us a new insight into disease, but the cellular pathology was never pushed to such a degree as the microbe. It is undoubtedly important that we should know the cause of disease, and so far as micro-organisms are concerned, we must accept all evidence which tends to connect them with disease as causal agents; but medicine cannot advance simply on bacteriological lines. There were brave men before Agamemnon, and there were great advances made in medicine before bacteriology was ever introduced, by the great clinicians who studied disease at the bedside, and who by marvellous powers of analysis were able to interpret the symptoms presented by individual cases, and to weld them into a whole. A system of therapeutics was established by the clinicians, which stands good even at the present day, and which was grounded on observation and experience; theory or guesses did not form such an important part of the old system of medicine. The germicidal theory of the present day, which rests on bacteriology, would have been rejected by the old clinicians, because they would have tested it at the bedside and found it wanting. The treatment of phthisis, cholera, pneumonia, gonorrhœa, have not been advanced one iota by the discovery of the bacillus tuberculosis, the comma bacillus, Friedlander's bacillus, or the gono-coccus of Neiser. This is to be regretted, though it does not absolutely discredit the researches which have been made on these micro-organisms; it simply shows that we have room for therapeutical research, and that the bacteriological key is not the key to the treatment of disease. There is room for clinical research, apart altogether from bacteriology, and there is room for therapeutical research apart altogether from bacteriology. Thousands and thousands of physicians are daily treating disease with success, on lines which might be pronounced old fashioned. They would gladly abandon their system if the new school offered them a richer choice of remedies, and a more successful one.

New Remedies.

New chemical compounds appear to be in greater favour at the present time, as possible new remedies, than those derived from the vegetable kingdom. *Hydronaphthylamine* — or more correctly speaking, *tetra-hydro-β-naphthylamine*—is one which has lately been experimented with, and is proved to possess remarkable mydriatic properties. According to Professor Filehne, of Breslau, if a little of a 5 p.c. solution is dropped into the eye, it causes dilatation of the pupil in the eye treated only; but if more be used, or as soon as any has become absorbed, the other pupil dilates also. Its power appears to be greater than that of atropine, since after the pupil has been dilated by a maximum dose of that alkaloid, it can be still further dilated by a maximum dose of hydronaphthylamine. It does not paralyse the contracting muscle like atropine, but stimulates the nerve terminations connected with the dilating mechanism.

Exalgine is the name given to a new analgesic, antiseptic, and antithermic compound, which is stated to have the constitution of methyl-acetanilid. It is met with in the form of needles, or large white tablets, according to the mode of preparation. It is very soluble in water containing a little alcohol, but is only slightly soluble in cold water, although more so in hot water. It is given as an analgesic in the dose of 0.25 to 0.40 gramme, or 0.40 to 0.75 gramme, in two doses in the course of twenty-four hours. Gastro-intestinal irritation, rash or cyanosis, has not been observed to follow its use, as is sometimes the case with acetanilid and antipyrin, except that in one case slight erythema occurred. The toxic dose has been ascertained to be 0.46 gramme per kilogramme of weight of the animal, death resulting from paralysis of the respiratory organs. In non-toxic doses pain disappears, but the tactile sense remains. Its antiseptic and antithermic action are relatively less important. A little light appears to have been thrown on the relation between the chemical constitution of some of the recently introduced chemical remedies and their physiological action. Antiseptic properties have been found to be characteristic of alcoholic hydrated derivatives, such as phenol, naphthol, etc.; antithermic properties prevail in amidogen derivatives—viz., acetanilid, kairn, and thallin; and analgesic properties are most pronounced in amidogen compounds, in which an atom of hydrogen has been replaced by a molecule of a fatty radical, especially of methyl, *e.g.*, antipyrin, acetophenacetidin, and exalgine.

Paraldehyde.—An important contribution to the clinical history of this hypnotic has recently been published by Dr. J. Gordon, of Aberdeen. He points out that it does not depress the heart's action; the dose does not require to be increased, since the same doses have produced hypnotic effects for months, and no marked craving for the drug follows its use. Its action is speedily produced, sleep generally occurring in ten minutes after its administration; it does not disorder the digestion, and is in many cases gently laxative. In the majority of instances the amount of urea excreted is increased, but the quantity of fluid constituents is diminished.

Myrtol, which was at one time recommended as an antiseptic, has recently been shown by Herr Jahns to consist chiefly of a terpene allied to that of oil of turpentine, and eucalyptol. Every purpose for which myrtol might be used would therefore be equally well served by eucalyptol. The latter body has lately been found to occur in several oils, such as those of santonica, cajuput, and camphor, the two last being comparatively inexpensive sources of eucalyptol.

Methacetin, a new antipyretic which has been used in the clinic of Professor von Jacksh, at Gratz, is reported on favourably. It is an acetyl compound of anisidin, being, in fact, para-acet-anisidin. It is prepared in the form of a pale, reddish, odourless, crystalline powder, having a bitterish saline taste. It is soluble in cold water, more so in hot; very soluble in cold and hot alcohol, and dissolves equally in acid and alkaline liquids. It melts at 127°C. It possesses antiseptic as well as antipyretic properties, a one per cent. solution being sufficient to prevent the decomposition of milk and ammoniacal fermentation. The lethal dose is shown to be, in the case of rabbits, three grammes, the action being very rapid, cramps in the hinder and then in the forward extremities quickly setting in, and the general course of poisoning closely resembling that of antipyrin. Doses of 0.15 to 0.20 gramme were found sufficient to reduce the temperature to the normal standard in children suffering from tuberculosis and pneumonia. The depression of temperature continued sometimes for several hours, and then gradually rose, and when the dose was given at the time of the physiological daily remissions, the fall in temperature was more rapid, and lasted longer. Free perspiration was produced in many cases in about half an hour after taking methacetin, but neither sweating nor lowered

temperature was noticed in persons not suffering from fever, to whom the drug was administered. Generally speaking, it is well borne by children; but in one case, collapse lasting for three hours followed a dose of 0.20 gramme given to a girl exhausted by tuberculosis. It is therefore recommended that the dose of 0.30 gramme for children should not be exceeded, and small repeated doses are considered preferable to a larger single one. The ready solubility and consequent rapid absorption of this substance render it necessary to use great caution in experimenting with it.

Di-thio-salicylic acid has recently been suggested as a substitute in some cases for salicylic acid. It is prepared by heating together at 120° to 150° C. equal molecular proportions of salicylic acid and sulphur chloride. The pale, resinous, fused mass first formed is dissolved in soda solution, and the di-thio-salicylic acid precipitated in the form of a resinous straw-yellow mass, by means of hydrochloric acid. When dried it is pale yellow, dissolves readily in spirit, benzol, and glacial acetic acid, and melts readily. The di-thio-salicylate of sodium is obtained on adding chloride of sodium to a concentrated solution of the acid, as a crystalline yellow precipitate, forming on trituration a pale yellow powder. Some years since (1876) it was suggested by the late Mr. John Williams that as the sulpho-carbolates possessed certain advantages over the carbolates, it might in like manner be possible that sulpho-salicylates might be preferable, under certain circumstances, to salicylates.

Sulphonal.—An interesting account of the effects of an overdose of sulphonal is reported from Germany. A workman in Riedel's factory took a good tablespoonful of the drug, with the view of procuring sound sleep. Half an hour afterwards, whilst drinking a glass of beer, he experienced so strong a feeling of lassitude that he went home to bed at once, without finishing the remainder of his beer. The dose was taken on a Saturday evening, and he slept until the Tuesday following, when he was violently roused, but went off to sleep again immediately. The next day he was again roused by his wife at one o'clock, and remained awake, though feeling giddy, until eight o'clock p.m., when he ate food with relish. On Thursday he rose at seven o'clock, and by the evening all the symptoms had disappeared. A drug which can procure such lengthened sleep promises to be of great use in cases of mania in which sleeplessness forms a prominent feature.—*Antipyrin* has been found to possess the property of increasing the solubility of some quinine salts. Thus one gramme of quinine hydrochlorate requires a temperature of 53° to 56° C. to dissolve it in two grammes of water; but if 0.40 or 0.50 gramme of antipyrin be added, it will dissolve at a temperature of 2 ° to 31° C.; or with 0.20 to 0.25 gramme added, it will dissolve at 44° to 50° C. The quinine antipyrin solution remains unaltered for a long time, but that of the quinine hydrochlorate alone crystallises at once on cooling. The insoluble valerianate of quinine behaves in like manner, one gramme with one to one and a half grammes of antipyrin dissolving in double its weight of water at 44° to 62° C. It is suggested that this property may find a practical application in the preparation (without the addition of acid) of a solution of quinine for hypodermic use. Attention has been directed by Messrs. Prudhomme and Vigier to the fact that when antipyrin and sodium salicylate are mixed together in the dry state, a decomposition takes place, an oily liquid being formed that renders the mass pasty, and which may in twenty-four hours constitute 10 per cent. of the whole. This pasty product is alkaline, although the salicylate of sodium normally has a faintly acid reaction. A solution of the two compounds does not appear to change in the same way, since the solution remains slightly acid. It appears, therefore, that until more is known of the compounds formed, it is undesirable to prescribe the two drugs together.

Strophanthus.—Further investigations have been made into the nature of the diuretic principle of strophanthus. This was stated by M. Catillon to be a calcium compound of a nitrogenous acid, and to be free from toxic action. Calcium strophanthate is now described as being tasteless and deliquescent, and turning litmus paper blue. A solution acidulated with hydrochloric acid gives a precipitate with potassium iodo-hydrargyrate, or sodium phospho-molybdate, and it is thought likely that the report that strophanthus seeds contain an alkaloid has originated in this reaction. The acid, which is believed to be of the nature of an amide, has been separated by treating the solution of the calcium salt with sulphuric acid until a precipitate ceases to form, filtering and precipitating with great excess of alcohol.

Hysteronica Baylanuen, a Chilian plant, employed in that country in gastro-intestinal affections, has been experimented with by Dr. Baillé. He has found an infusion made with one part of the plant and 150 of water to be an excellent remedy in diarrhœa, and useful in acute and chronic dysentery. It appears to owe its activity to a brown acrid resin and an essential oil, since no alkaloid has been found in it. The whole plant is covered with a yellow, odorous, resinous exudation.

Ormosine is the name given to an alkaloid extracted from the seeds of *Ormosiæ dasycarpa*, a native of Venezuela and British Guiana. The alkaloid is stated to have a narcotic effect resembling that of opium (Kobert. Jahresb, 1886, p. 59), but has not until recently been obtainable as an article of commerce. Further experiments are still needed to determine whether it can be used in cases in which opium is not applicable.

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. KESTEVEN, M.D.

The Use of Electricity in the Treatment of Diseases of the Female Pelvic Organs. By J. Wesley Bovee, M.D., Washington (*Journal of the American Medical Association*, April 13th, 1889).—"Great claims," Dr. Bovee observes, "are being presented for the efficacy of the galvanic current in dispersing fibroid tumours of the uterus. . . . Its value in this direction is, I believe, overrated." In two cases that Dr. Bovee diagnosed uterine fibroids, the growths disappeared after several applications of the electric current. In another case of multiple fibroids of the uterus, the Faradic current was employed, the tumours also disappeared. Dr. Bovee's comment upon these is thus: "I believe, however, that the electric current was not the real factor in their removal, inasmuch as these growths frequently disappear without any treatment whatever." In another case Dr. Bovee believed the diagnosis to have been incorrect, that no tumour existed, and that possibly hypertrophic thickness of the posterior wall of the uterus was the enlargement. As a reason of this opinion Dr. Bovee states that he has treated a number of cases of patients suffering with uterine fibroids, diligently for months, without any diminution in size of the growths, and further observes:—

"At any rate, I cannot see what reason the advocates of 'electrolysis of fibroids' have for so terming the electric action they describe. Certainly no breaking up of the chemical constituents of the growths occurs, except, perhaps, some simple salt like sodium chloride is decomposed. But the albuminoids and other complex proximate principles are not broken up, consequently electrolysis does not occur. Even if it does take place at the poles chemical change does not extend any appreciable distance into the growth. In hard fibroids of from nine to twelve inches in diameter, I cannot conceive how any electrolytic action can take place through the tumour, with irreparable damage to the delicate adjacent tissues. How can a current so powerful be confined to the growth when the surrounding more delicate tissue has so much greater conductivity."

Dr. Bovee remarks, "The galvanic current has been used considerably in the treatment of inflammatory deposits about the uterus, punctures having been made and powerful currents used as in the treatment of fibroids. I believe mild currents, if applied oftener and longer, both in duration of application and period of treatment, will prove more serviceable." This has been the plan of treatment of the cases related in this paper, and none which he thinks might wisely be substituted for the knife in diseases of the ovary and oviducts. The author further states that he believes that had Mr. Tait given electricity a fair trial in his own practice, he would not have reported his second thousand of consecutive abdominal sections. There is a class of cases that cannot tolerate the application of electricity—not even the amount of electromotive force just sufficient to overcome the resistance of the tissues through which it passes. I am unable to see anything about these patients that could, in any respect account for the intolerance of the current. It is probably an idiosyncracy that will only be known after attempts to apply the current have been made. The batteries I have

used were made by Waite & Bartlett, of New York, and have been faithfully cared for. I have usually applied the galvanic current just strong enough to be not uncomfortable to the patient. Each séance usually lasted from fifteen to thirty minutes, and usually repeated on alternate days, but occasionally, applications were made every day. The treatment was usually supplemented by tamponnement with small woollen pledgets that were left *in situ* until just before the patient was to return for another treatment. The galvanic current was used in every case, and occasionally the faradic current was employed for its tonic effect, and for the relief of pain. It was usually successful in both of these, and its salutary effect upon constipation was occasionally noticed. I do not think much good will come from the use of electricity in large pelvic abscesses or in tumours of a cystic or malignant nature. But I think nearly all other diseases of the female pelvic viscera are amenable to its restorative influence. Even small abscesses and small cysts of these structures are, I believe, curable by the judicious application of this remedy. In many of the cases that have been reported as cures of ectopic gestation by electricity, the condition of the patient's pelvic organs previous to the discovery of the so-called pregnancy had not been known.

Histological Examination of a Meningo-Encephalocele (*Le Progrès Médical*).—M. Perier, at the sitting of the Academy of Medicine, Paris, April 2nd, related the case of an infant who, at birth, presented on the middle line of the occipital region a tumour, which in three weeks had reached the size of an orange, was soft, but not pulsating. After its contents had been removed by aspiration, the pedicle was tied and the tumour removed. The child recovered in eight days. M. Rauvier found in the mass of cellular tissue, portions of nervous substance derived from the cerebrum cerebellum, together with the tissues of the ependymer, chorid plexus, and meninges.

On the Equino-telluric Origin of Tetanus. By M. Verneuil (*Le Progrès Médical*, April 6th, 1889).—At the sitting of the Academy of Medicine, Paris, March 26th, M. Verneuil submitted the following conclusions on the question. 1. Tetanus is transmissible, not only between animals of the same or different species, but also from man to man and from man to animals, and *vice versâ*. 2. The demonstration is established as regards solipedes. 3. The contagion from horse to man may be made directly or indirectly, the latter being most frequent. 4. Intermediate agencies, whether in prolonged or slight contact with a tetanic horse, receive without destroying the poisonous element, consequently enlarging the sphere of infection. 5. Living beings may serve as the means of transmission without being themselves affected, but are constantly in danger of traumatic auto-inoculation. 6. A wounded man may receive infection of tetanus from surrounding objects, but of all these the horse and all his belongings are the most dangerous. Next in order is cultivated ground and its products. 7. The earth case acquire tetanic virus when contaminated by a tetanic horse. 8. Statistics show that tetanus occurs most frequently among those persons whose calling brings them in contact with horses—that human tetanus is parallel with equine. 9. The equine theory is confirmed by a majority of facts.

Therapeutic Employment of Eschscholtzia Californica (*L'Union Médicale*, April 30th, 1886).—This plant, of American origin, is a Papaveracea, from which alcoholic and aqueous extracts are prepared. A minute quantity of morphia is contained in the glucose extract, and a base to be yet determined which has a powerfully poisonous influence over cold-blooded animals. Physiologically, this Eschscholtzia acts—1. On the respiration: with initial acceleration, followed by retardation to the fatal termination. 2. On the temperature: this is raised by the simple extract, but is lowered by extract deprived of resin. 3. On the nervous system: in small doses, loss of spontaneous action; in larger doses, the bulvar and medullary functions are extinguished. Clinical observations have been made upon thirteen individuals; two cases of chronic bronchitis, two of advanced tuberculosis, one of Bright's disease, one of nephritis, two of disease of the liver, one of paralysis agitans, one of neuropathy, and two of rheumatism. The effects have resembled those of morphia, without any of its inconveniences. The dose of the plant is from 2½ to 10 grammes per *diem*; that of the alcoholic extract from 0.81 centig. to 12 gr.

Ill Effects of Antifebrine (*L'Union Médicale*, March 21st, 1889).—M. Cheron records a case of neurasthenia in which, after eight doses had been taken with impunity, there occurred, after the ninth dose, a concurrence of dangerous symptoms which could not be explained by the cumulative action of minute doses. An hour after the ninth dose was taken, profuse sweating occurred, with serious and alarming collapse. The cheeks, which previously had been red, became pale and cyanosed, the extremities cold, the pulse threadlike and intermittent, respiration rapid. By injections of ether every five minutes, the application to the surface of hot linen, and the administration of hot coffee, with brandy, the danger gradually passed away. In another case, Kronecker observed rigors occurring at the end of eight hours. Collapse also had been witnessed, but less severe, after a few repeated doses, with profuse sweating.

Observations upon Blood-pressure (*L'Union Médicale*, April 27th, 1888).—Professor G. See has given, at the close of his papers upon arterial tension, the following clinical and therapeutical applications of his observations, as deduced also from the researches of M. Basch:—1. Insufficiency of the mitral valves is attended with diminution of pressure. 2. Arterial sclerosis induces increased blood-pressure. 3. In chronic nephritis, with hypertrophy of the heart, pressure exceeds the normal amount; where hypertrophy is absent the blood-pressure is found to be normal. 4. In most cases of fever the pressure is augmented; it falls with the decline, and rises again to the normal degree during convalescence. 5. As a general rule the degree of pressure depends upon the quantity of blood sent to the aorta at one time, together with the resistance that the blood experiences in the arterial system. . . . . 7. In mitral insufficiency the pulse is soft; in aortic insufficiency it is sharp.

Propagation of Cancer, locally (*L'Union Medicale*, March 21st, 1889).—Cancer has spread with unusual intensity in a certain district of Normandy, inferring the presence of a local cause. This has been assigned to the impurity of the water used in the manufacture of cider, which is almost the exclusive beverage. As a preventive it is advised that the water should be boiled, or have the addition of a small proportion of sea salt.

Local Treatment of Diphtheria with Sulphuret of Calcium. By Dr. Hubbard (*L'Union Médicale*, March 21st, 1889).—A solution is prepared in the following manner: Lime, one part; sulphur, two parts; water, twenty parts; boil until the quantity is reduced to twelve parts. To be used with the spray every half-hour, or less frequently, according to the severity of the case. For infants, a small quantity of water is to be added. A change in the false membrane is rapidly induced, and general amendment follows. In some cases the membrane had entirely disappeared in one day. This notice is quoted from the *Medical Record* and *Gazette Médicale de Liège*.

Abortion of Mammary Abscesses. By M. Budin (*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, April 21st, 1889).—M. Budin considers that he can abort mammary abscesses by disgorging the lacteal canal, in submitting the nipple to certain methodical pressure by which the fluid is expelled from the ducts. These proceedings of M. Budin are virtually those ordinarily practised for drawing off the milk. The thumb and index finger are applied at a certain distance from the nipple, near the circumference of the areolas. Pressure is first made from the surface towards the base; then continuing the pressure, the nipple is to be compressed from behind forward, so as to expel the purulent contents of the lacteal canals.

Treatment of Uncontrollable Vomiting in Pregnancy. By Dr. Gunther (*L'Union Médicale*, March 21st, 1889).—A moistened sponge, attached to the positive pole of a galvanic pile, is to be inserted into the vagina, and placed in contact with the cervix uteri. The negative pole, represented by a metal plate, is to be placed over the space between the eighth and ninth dorsal vertebræ. Weak currents, of short duration, are then to be passed.

Treatment of Pulmonary Tuberculosis by Biniodide of Mercury (*L'Union Médicale*, March, 1889).—MM Miquel and Rueff, for the above purpose, employ the following with the spray: Biniodide of mercury, one gramme; iodide of potassium, one gramme; distilled water, 1,000 grammes. Out of twenty-seven cases, nineteen had been benefited, and eight remained as they had been.

II.—SELECTIONS FROM CONTINENTAL MEDICAL JOURNALS.

By G. F. Cadogan-Masterman, M.D.

A New Mode of Magnetic Extraction.—By Dr. Victor Melcior (*Revista de Ciencias Médicas*, Barcelona.) The lodgment of minute particles of foreign matter, especially of iron, in the eye is one of the commonest of accidents. But, whether we regard the excessive pain or the possibility of fatal mischief to the ocular apparatus, the mischance is one which cannot be lightly regarded, especially if the splinter be lodged in, or has perforated, the cornea. A young ironfounder consulted the author at the beginning of the present year, two scales of metal having lodged so firmly that it was beyond the resources of domestic surgery to extract them, and the eye had become terribly inflamed under its rough application. On examining the eye there was found intense conjunctivitis and photophobia, and just below the inferior

perimeter of the cornea a minute black speck could be seen, and in a swollen fold of the conjunctiva above there was a second. As the particles were evidently of metallic iron a magnet suggested itself as the best and safest extractor, and on applying the edge of one pole to the speck on the cornea it was instantly removed with only momentary sharp pain to the patient; but that in the sclerotic could not be managed so easily: it was too firmly implanted to be drawn by slight attraction, and the thickness of the magnet—probably a common "horse-shoe"—prevented its close application. Dr. Melcior, therefore, took a Weber's eye-scoop, rubbed it across the magnet three or four times, and then touched the splinter with it; it adhered. and with a little careful manipulation was triumphantly withdrawn. It may be mentioned that, when there is a Lechanché, or a bichromate cell at hand, a spiral of fine covered copper wire wound for an inch or so on a knitting-needle, or a French wire nail, makes a most efficient electro-magnet for the purpose.

Immunity from Phthisis enjoyed by Lime-burners, with Therapeutic Suggestions. By Dr. Halter (*Giornale Internazionale delle Sciencie Mediche*).—The author during a recent residence in Lengerich (Wurtemberg) noticed, as several other medical men had before him, that the men employed in some large lime-kilns there are singularly free from phthisis, whilst that disease is very prevalent amongst the population of the neighbouring town and district. In endeavouring to discover the cause of this immunity from one of the most fatal of disease it appeared to him that four points had to be taken into consideration. The purity of the mountain air where the works are situated. The extreme dryness induced therein by the hygroscopic action of the lime. The high temperature borne by the men who work around and within the kilns. And, lastly, the chemical action of the lime dust itself, which is so freely inhaled by the workmen. On the first point little need be said; the advantages to consumptives of breathing pure cold mountain air free from dust and animal emanations are too patent, and now too generally recognised to require more than passing notice; it may be pointed out, however, that although sufferers in the early stage of the disease are greatly benefited, if not absolutely cured, by residence at these high altitudes, the habitual dwellers therein are not free from its attacks. Therefore dry, cold air is rather curative than prophylactic, and living within its zone alone could not explain the immunity of the lime-burners. Its extreme dryness in the vicinity of the works cannot be, nevertheless disregarded. Researches carried out in England by Bowditch, Milroy, and Buchanan have shown how important is the condition of the soil and subsoil in reference to moisture in the generation of this disease, its relative amount in given areas being almost in direct ratio to the dampness of the earth. But, of course, in a space so comparatively small as that in question this condition could hardly extend far, or be very independent of that of the surrounding atmosphere, and might be taken as a factor of minor importance in the general result.

The lime dust itself might be expected to have considerable influence for good or evil, and *à priori* the latter. For it is in such a fine state of division that it penetrates within the cases of watches in the men's jackets, and must be inhaled very largely; and it is popularly believed to be very injurious in the way of provoking bronchial mischief amongst plasterers and bricklayers; but Nerkel has shown that the chief sufferers are those who are employed in pulling down old houses, and in their case it is not so much the dust of the mortar as of the dirt and filth intermixed with it which is so hurtful. The fact is, that the labourers at Lengerich are not injured by it, they are breathing it all day long and seem none the worse for it, and the autopsies of some who had died revealed no calcareous deposits in the lungs. There remains, then, only the high temperarure of the air within the kilns to be considered. The inhalation of superheated air in the treatment of pulmonary consumption is already known to us, and the observations of the author have been anticipated by others, but, as the method is of very recent introduction, a summary may be given. The basis of the system is, that the bacillus of phthisis cannot support a temperature much raised above the normal point, whilst the patients can. Moreover, the former are extremely intolerated of dry air at any temperature; whilst with us the drier the air is the higher it may be heated before it becomes unbearable.

Dr. Halter found that within the kilns where the men were working the heat ranged from 122° to 158°; whilst the air was almost absolutely dry, even at some distance from the furnaces it contained only half as much watery vapour as that outside. All of which is exceedingly bad for the pulmonary microbes. And it is obvious that air so hot and dry as this cannot contain any living forms of them. There is another point: the tolerance of a temperature so much above that of the healthy body is due to excessive evaporation from the skin and lungs; a man whose internal temperature approached 122° would soon be in as bad a case as the bacillus, but the excess of heat becomes latent in the perspiration he is exuding, and he is, for a considerable time, none the worse for it. But, to provide for this, the circulation must be quickened, the heart beat faster, metabolism and cell-change of all kinds be accelerated, and effete material be excreted more rapidly than usual. Therefore, pathogenic bodies, whether microbic or ptomainic, would be hurried out of the system or incinerated, like rats in a burning house, and even the phagocytes would be hard put to it to avoid destruction. In order to afford our phthisical patients the advantages of this plan, it is not, happily, necessary to turn them into lime-burners, nor to frequent the kilns; the little-used dry-air Roman bath—in contradistinction to the Turkish which is essentially a steam bath—yields all its advantages without its inconveniences, and is far better in every way than the mere inhalation of hot air through a tube and mouthpiece. And the author suggests a stay therein for fifteen to thirty minutes once or twice a day. The temperature should be from 41° C. to 55° C. (105.8° to 131° F.), which is higher than the bacillus can support. When a tube is used conveying superheated air, there is liability to scorching of the mouth, on one hand, or not raising the temperature sufficiently, on the other; in the hot air chamber both these defects are avoided. As regards the extreme temperature supportable by ourselves, Dr. Halter states that he has breathed air heated up to 120° F. (288° F.) with little inconvenience, and it was only when it reached 190° C. (406° F.) that it felt painfully hot. We naturally compare these astonishingly trifling effects with the impossibility of bearing contact with water heated above 50° C. (122° F.), but the difference is due to the fact that the conductivity of air for heat is only one fourth of that of water. It is much the same as when we carry a bottle filled with water just below the boiling point in our hands, without inconvenience, if it be wrapped in flannel. The expansion of the air by the heat occasions some distress in breathing it, for we have the conditions of respiring rarified as well as superheated air. No special building is necessary for the more moderate temperatures; a slow combustion stove in a small room would readily furnish it. The duration and frequency of the use of the bath depends upon the conditions of the patient and the stage of the malady. A fairly strong man in the early stage of phthisis should take it at temperatures of from 45° to 50° C.; one weaker or more gravely effected should not pass beyond 45°, and those in the later—that is, hopeless—stage should not be permitted to try it at all. When there is much feverishness or hæmoptysis it is inadmissible. Sufficient ventilation must be provided. It is better to breathe by the mouth only, for the hot air irritates the nasal passages. Forced breathing must be avoided. It is suggested that inhalations of creasote should be practised in the intervals of the hot-air bath. The bacillus of tubercle is very tolerant of low temperature if not dried at same time, —87° C., and even —130° C. in ice did not kill, but dry air, whether very hot or extremely cold, is fatal. This explains the success of Dr. Worms, of Riga, who keeps his consumptive patients in cold, dry air almost day and night, as well as that of the hot-air bath of equal aridity. But the percentage of deaths from the disease remains pretty constant.

Apuntes Médicos de Marruecos. By Dr. Ladrón de Guevara (*Revista de Ciencias Médicas*). An article extending through four numbers of the *Revista* gives a very readable sketch of the position of medicine and hygiene amongst the Moors in ancient and modern times. The greater part is chiefly of antiquarian interest; whilst it shews that the state of Tangiers and the larger towns throughout the kingdom of Morocco at the present day is deplorable in all respects. Under the worst of Governments, with no security for life or property, and with every hygienic condition neglected or defied, the lot of the people is miserable beyond description. And it is strange to find amongst a nation once the pioneers of science and literature in Europe, which possessed such scholars and teachers as Averhoes, Avicenna, and Rhasis, that medicine has fallen to the very lowest ebb, and that there is no medical school of any kind in the country. Anyone can practise it who pleases, and its professors are the most abject of men. The chief surgical operations are circumcision, the extraction of teeth, cupping and bleeding; and the medicines—opium, hàshish, a few drastic purges, astringents and reputed aphrodisiacs; whilst the sale of poisons for criminal purposes is almost openly carried on.

The writer was present one day in Tangiers when an old man, clad in a dirty turban, a ragged cloak and drawers, with bare feet and legs, was haled before the judge by a group of screaming and wildly-gesticulating women, who charged him with maltreating the head of the family. The wretched *hakim* had been engaged to open a vein at the corner of the man's eye. Heaven only knows what he had done, but the patient had become blind and epileptic. The accused threw himself on the ground, and passionately pleaded that he had done his best; that this very operation was the source of all his fame and reputation; that it always did good, and that the man's condition was "his fate," which he was bound in Islâm to accept with resignation. This argument placed the *cadi* in a dilemma, but, after angrily twisting his beard

for a minute or two, he got out of it by silently motioning a couple of ferocious looking soldiers to drag the defendant off to prison. The poor old doctor seemed glad enough to go, as it probably saved him from being torn to pieces by the infuriated women. In a few days he was released more ragged and dirtier than ever, and Dr. de Guevera recognising him in the street, invited him to his house in order to shew him some European instruments and medicines. In return, he produced from a leathern bag his own *armamentarium*. It consisted of a very sharp razor, two or three hooks, some clumsy pincers, and a chisel. He had also a surgical museum comprising more than 300 prepuces wrapped up in rags, and nearly a peck of extracted teeth. Looking at his tools and then at these memorials of his workmanship made the doctor shudder with their accumulated horrors. His pharmaceutical establishment was contained in a few dirty and most evil-smelling tin boxes. One day a brother of the craft was seen in the act of wrenching out an aching molar *al fresco*, with the aid of four volunteer assistants and a pair of farrier's tongs. Two of the former held the patient's head, two sat on his legs as he lay on the ground and grasped his hands, whilst the operator stood astride of him and tugged at the tooth with both hands. With a mighty yell from the sufferer it suddenly parted company, and down came the operator—whose foot slipped at the critical moment—plump on the prostrate victim as he fainted away with the redoubled agony. Circumcision is performed with a single cut with the razor, and the uvula is frequently removed in the same way. Gunshot wounds are treated by pouring in frizzling oil, and the rare operation of amputation is a circular sweep with the knife, sawing the bone through at the same place, and dipping the stump in melted pitch—most ancient of styptics !

The Treatment of Disease by Bacteriotherapia. By Dr. Luis Manfredi (*Giornale Internazionale delle Sciencie Mediche*).—The conception of Hahnemann was the treatment of diseases by minute doses of medicines which produce effects which resemble them. The newest departure is the treatment of diseases, or rather their causes, with each other. Bacteriotherapy is the art of removing or averting mischief due to bacteria by the administration of other similar organisms inimical to their existence. Its foundation is the magnificent idea that in the mutual antagonism of these surpassingly minute beings we have, in a microcosm, a struggle for existence as fierce and unrelenting as that in our own greater world, and in which the survival of the fittest ensures health to their involuntary host. Although the microscope shews us that all their encounters are not gladatorial (some dictated by gentler feelings being examples of symbiosis), yet the general result is, in whatever cultivant they may be brought together, the triumph of one or a few, and the utter rout and disappearance of the rest.

We are chiefly indebted for the idea to Raulin, to whom belongs the credit of the profound investigations into the life history of *aspergillus niger*, and, also, to Naegeli, who extended to others of these minute beings the same accurate examination. From both we learn that the essential point with them, as with our own teeming millions, is the supply of food. They do not devour one another literally in this internecine war, but only prevent their rivals obtaining aliment, just as we do and call it healthy competition.

For instance, aspergillus is being cultivated in Raulin's solution, which is composed only of mineral substances, and the zinc it contains in the proportion of 0.023 gramme per litre is suppressed—the plant dies. And the same result follows if we introduce another mould with a special zinc appetite—it is starved to death. Raulin's solution contains a trace of iron, which he has shewn the fungus does not use as food, and yet cannot live without, because it combines with some noxious matter, which the latter excretes, and renders harmless. But if we put in some other cells with a taste for iron, the aspergillus dies once more, but from autotoxia, not starving. From these two facts, already classical in scientific annals, two theories have emerged which explain not only why bacteria destroy each other, but why certain soils, the human body included, passively resist invasion by two contemporaneous hordes—it declines to feed them. A bacillus may destroy another, either by appropriating its food or its natural physic—we may say—when it happens that what is meat to one is an antidote to the other. And there is yet a third, and the more generally accepted, theory that certain bacilli can generate a diastase which dissolves their rivals into a broth they themselves feed upon. This is known as phagocytism.

But, in the case of the disappearance of both organisms, when two species of bacilli are implanted together in the same soil, can we be sure that the one has really devoured the other? It is a matter of history and scarcely to be doubted that the *feles Kilkennyensis* did so, but in that instance the *locus in quo* had no influence upon the result; but Raulin shews that the slightest change in the composition of the nutrient medium may render it unfit for the sustentation of a given bacterium. Therefore, may not some change, scarcely appreciable to ourselves, have determined its destruction synchronously with the arrival of, but not potentially due to, the second organism? For these minute bodies do not merely die, the greater number absolutely disappear at the same time. Our present knowledge, however, of antagonism amongst these being almost infinitely small, is that which we might have of a polyhedron of which we have seen and measured only one or two angles. Be that as it may, the fact that a nutrient medium in which certain growths have lived and died cannot be again used for the cultivation of the same kind, or even of others, goes far to explain the immunity which one attack of a non-recidivous disease confers upon us. We may imagine that during the first attack, the body lost or acquired *something* necessary or inimical to some form of bacterial life, and which is never again replaced or got rid of.

The earliest form of bacteriotherapy—although practised empirically—was the Jennerian vaccination, but we cannot be quite sure if the virus in the lymph be that of variola in some modified form, or that of an antagonistic organism. It is, of course, only in the latter case that it can truly be called so. Pasteur, however, has shown that the bacillus of cholera preserves fowls from infection by carbuncle. The one disease above all others which would seem the most promising for treatment in this new way is tubercle, and Dr. Cavagnis, of Padua, believed that he had succeeded in doing so by modifying the bacillus of Koch by cultivation in peptonized broths mixed with a small quantity of phenic acid. The plan on the face of it was unreasonable, and, after the publication of his first paper, he found that his experiments had misled him, and in a second he frankly acknowledged his error.

(To be continued.)

III.—NOTES FROM FRENCH JOURNALS.

By H. R. Hatherly, M.R.C.S.

Removal of the Entire Humerus (*Journal de Medicine*).—M. Polaillon has exhibited before the Société de Medicine Pratique a left humerus which had been removed by him under the following circumstances: The patient, æt. fifty, received a gunshot wound in the upper portion of the left arm at the battle of Solferino on the 24th June, 1855. From time to time splinters of bone were removed, and at the end of twelve months he was cured. The wound remained healed for seventeen years, but at the expiration of this long period suddenly an abscess formed in the arm, a fistula remained, and by degrees the humerus was affected with osteo-myelitis throughout the entire length. The patient endured this osteo-myelitis for twelve years, but the humerus having broken mainly through muscular action, Dr. Polaillon was consulted. He removed the whole of the humerus at two sittings. The operation was perfectly successful, the patient making a good recovery. The humerus has not been reproduced, but the arm is limp and shortened. Supported by a splint of leather, or other material, the patient can execute all movements of the shoulder and elbow, and he has the important advantage of retaining the whole of the movements of the hand.

Hospital for Medical Students at Vienna (*Le Progres Medical*).—A society has just been formed at Vienna to provide for the comfort of students who are ill. A hospital is about to be established for their accommodation.

International Congress of Therapeutics and Materia Medica (*Le Progrés Medical*).—This congress will take place at Paris from the 1st to the 5th of next August. It will be open to all medical men, chemists, and veterinary surgeons who send in their names and subscription fees of ten francs. There will be two sections—one devoted to therapeutics; the other to materia medica. Amongst other questions the following are set down for discussion:—1. Antithermic and analgesic remedies. 2. The antiseptics best adapted for each species of pathogenic microbe. 3. Cardiac tonics. 4. New vegetable drugs recently introduced as therapeutic agents. 5. Uniformity of weights and measures employed in formulæ, and the utility of an international pharmacopœa.

Explosive Medical Compounds (*Revue Scientifique*).—Professor Kobert has drawn attention to some medical compounds which may sometimes cause explosion. Chlorate of potash mixed with charcoal tooth powder may explode even in the mouth. Chlorate of potash pounded in a mortar with catechu, nut-galls, or tannin is liable to detonate, even if glycerine be added. Chlorate of potash will detonate whilst being mixed with phosphate of sodium. One part of chromic acid mixed with two of glycerine explodes immediately. Iodine mixed with ammonia forms a very explosive compound. If alcohol be mixed with bromine, a bromide of ethyl is formed which frequently explodes. Picric acid reduced to powder detonates if mixed with anything else. Nitro-glycerine is liable to explode even when much diluted.

A New Journal *(L'Union Médicale).*—A new review has been commenced under the editorship of Dr. Henri Tournier, which will be called "*Journal des Maladies Cutanées et Syphilitiques.*" The work is intended to be of a practical character, and it is hoped will render the study of dermatology and syphilography more popular.

Salicylate of Mercury in Venereal Disease *(Journal de Medicine).*—Dr. Plumert gives the following account of the use of salicylate of mercury in venereal diseases. It is a white amorphous powder without taste or smell, and its reaction is neutral with litmus paper; it is nearly insoluble in water, but the addition of a little chloride of sodium or carbonate of potash renders it soluble. It is used as an injection for blenorrhagia, the formula being salicylate of mercury and carbonate of potash, of each one to three grammes, distilled water a litre. In cases of ulceration of venereal origin and in phymosis, the parts may be dressed with compresses dipped in a one per cent. solution of the salicylate, or with an ointment consisting of one part of salicylate of mercury to thirty of vaseline, which is also a useful remedy for eczema. When there is copious discharge from balanitis or vulvitis the parts may be dusted with one part of salicylate of mercury mixed with twenty parts of carbonate of magnesia; it will be found to lessen the discharge. In syphilis, salicylate of mercury may be administered by subcutaneous injections, or in pills. The solution is made by dissolving a decigramme of the salicylate and of carbonate of potash in ten parts of boiling water. The solution should be prepared as often as it is wanted, and should be colourless and free from deposit. A cubic centimetre should be injected subcutaneously, and deep into the cellular tissue. The injection only causes pain some minutes after it has been made. Stomatitis is only caused when the treatment is prolonged. The pills contain a quarter of a gramme of the salicylate, and from two to four are given daily, exceptionally, six may be given.

IV.—NOTES FROM RUSSIAN, POLISH, BULGARIAN, AND SWISS JOURNALS.

By VALERIUS IDELSON, M.D., BERNE.

On the Phosphorus Treatment of Rachitis.—At the third general meeting of Russian practitioners at St. Petersburg, Dr. Anna N. Shabanova, house physician to Prince of Oldenburg's Hospital for Children, read a paper (*Transactions of the Meeting*, No. 2, 1889, p. 55), detailing her experience in regard to Kassowitz's method of treatment of rachitis by the internal administration of phosphorus in small doses. The total number of her cases amounts to 105, of which 30 refer to children under one year of age; 56 to those aged from one to two; 12 of from two to three; 6 of from three to seven; and 1 of five. In 98 defective height was present, the *minus* (comparatively with the standard) varying between four and seventeen centimètres. In 58 the body's weight was sub-normal, the *minus* oscillating between 320 and 1,060 grammes. Out of 105, in 90 cases both the patient's height and weight increased during the treatment (which lasted, in individual cases, from one to eight months), the *plus* in the former case varying between two and twenty-six centimètres, and in the latter between 600 and 900 grammes. The increase was most marked about a third year of life. The following forms of rachitis were observed: cranial lesions alone in 15 cases; cranial and thoracic ones in 12; cranial, thoracic, and spinal, in 9; craniotabes and lesions of the chest and limbs in 13; lesions of the skull and limbs in 9; those of the chest alone in 1; of the chest and limbs in 25; of the chest, spine, and limbs, in 9; of the limbs alone in 6; of the whole skeleton in 14; laryngospasmus in 20; convulsions in 10; retarded dentition in 68; retarded involution of the major fontanelle in 38; retarded walking in 30; general nervous irritability in 82; dyspepsia in 30; bronchitis in 28. In 29 patients rachitis was complicated with scrofula, in 48 with anæmia, and in 2 with syphilis. The therapeutic results are classified by the author as follows: In 6, "excellent" ones were obtained; in 32, "good;" in 39, "fairly good;" in 22, only "slight improvement" was noticed; while in 6, the disease "grew worse" under the treatment. Dr. Shabanova's general conclusion is to the effect that "the phosphorus treatment of rachitis gives, on the whole, fairly favourable results, bringing about a marked amelioration of the patient's general state, and even that of various individual manifestations of the disease; in particular, the treatment proves relatively most successful in regard to nervous symptoms; a second place is occupied by motor defects of the limbs, and a third one by osseous lesions."

Dr. Shabanova's communication has given rise to a rather lively discussion, in the course of which Dr. N. K. Viajlinsky, of St. Petersburg (*loc. cit.*, No. 10, p. 397), has expressed his doubt whether the lady is justified in attributing the improvement noticed by her solely to the action of phosphorus alone. Various hygienic and dietetic measures adopted by her most decidedly largely contributed to the favourable results obtained. As a matter of fact, Dr. Viajlinsky treats rachitis more or less successfully by baths and cod-liver oil, without resorting to any medicaments.

Similarly, Dr. Lev P. Katchenowsky and Professor V. F. Jakübovitch, of St. Petersburg, emphasize that, to verify her conclusions, Dr. Shabanova ought to have carried out a parallel series of controlling clinical experiments, omitting phosphorus, but leaving all other conditions equal.

Dr. Alexandr A. Kïsel, of St. Petersburg, rejects the phosphorus treatment of rachitis altogether, and that on the following grounds:—1. Phosphorus belongs to the category of most powerful poisons. 2. As some physiological experiments of his own have proved, the substance does not cause any increased deposition of lime salts about the osseous system in young (growing) animals. 3. Hence, the starting-point for the method in question is totally wrong. 4. In addition, the doses used are exceedingly high. 5. Before venturing to administer any poisonous remedy to children, its innocuousness (in medicinal doses) must be previously clearly proved by physiological evidence; meanwhile, nothing of the kind has been yet done in regard to phosphorus. 6. Any improvement observed in rachitic children in the course of the phosphorus treatment by no means can constitute anything like an evidence in favour of curative effects of the drug, since (*a*) hygienic and dietetic measures alone, invariably resorted to simultaneously with the use of phosphorus, do most decidedly manifest a beneficial influence on the course of the disease; (*b*) in a majority of cases, rachitis shows a pronounced tendency to a spontaneous improvement; (*c*) rachitic children continue to grow in size and weight, independently from any treatment.

On Malarial Hæmaturia.—Dr. Molloff, of Sofhia, Bulgaria, relates (Bulgarian bi-weekly *Meditsinskï Preglëd*, Nos. 1 and 2, 1889, p. 22) a rare and very instructive case of larvated malarial poisoning, closely simulating vesical stone. In a boy of seven, who had formerly resided at a malarial village, but never suffered from intermittent, there had suddenly appeared hæmaturia, frequent painful micturition, vesical tenesmus, sacral pain, and sleeplessness. His urine proved to contain red blood-corpuscles, hyaline casts, and albumen. No stone, however, could be detected in the bladder, and the treatment by hot baths, diuretics, and emollients, utterly failed to relieve the symptoms. While watching further over the case, Dr. Molloff made at last the important discovery that the boy was visited daily by febrile paroxysms, beginning with rigors about noon, and ending with profuse sweats towards the evening. The spleen proved to be enlarged. Hydrochlorate of quinine was at once administered, with the result that in two or three days all the symptoms disappeared tracelessly and permanently. Dr. Molloff believes that his case is yet unique in international literature, and represents a peculiar variety of malarial poisoning, which he proposes to name a "*febris perniciosa hæmatodysurica.*"

Mechanical Treatment of Gleet and Sexual Astenia.—In the Polish Monthly, *Wiadomosci Lekarskie*, No. 6, 1889, p. 169, Dr. Karol O. Szadek (pron. "Shadek"), of Kïev, publishes an able and interesting paper on the treatment of inveterated gleet by the introduction into the urethra of Beniqué's duly curved tin bougies (eleven centimètres long), anointed with either Unna's salve (℞: Olei cacao, 100 grammes; ceræ flavæ, 2.0 to 5.0; argenti nitrici, 1.0; balsami Peruviani, 2.0. M. f. ung.), or Sperling's (℞: Lanolini, 20.0; ceræ albæ, 4.0; argenti nitrici, 0.1 to 0.3. M. f. ung.). In nervous or very sensitive subjects, in whom the insertion of the bougies gives rise to pain and erection, a from 3- to 5-per-cent. solution of cocaine should be previously injected into the urethra. During the first sitting the bougie is left *in situ* not longer than for three or five minutes, but later on the duration of the *séances* are gradually increased up to fifteen or even twenty minutes. The sittings are repeated every two or three days, except very inveterated or atonic cases, in which a daily introduction of the instrument is advisable. As to the size of the latter, the author uses a set from No. 18 to No. 30 Charriere, commencing with the least irritating bougies and gradually ascending to even larger ones. In relatively recent and mild cases he usually employs Nos. 20, 21, and 22, while in more severe and more protracted ones (which, by the way, constitute a vast majority) he, following Professor Otis's instance, passes by degrees to No. 28, or even No. 30. In patients with narrowed meatus, he enlarges the latter by means of a bistoury or scissors. In such cases where the lesions are situated in the posterior division of the urethra, Dr. Szadek introduces his bougies even as far backwards as the bladder. According to his experience the deep insertion, when practised with due caution and carefulness, never causes any untoward accessory effects (such as vesical or urethral irritation, etc.). In all, thirty cases of neglected gleet were treated after the mechanical method. In three of them, referring to unusually severe or old morbid changes about the urethra, complicated

with obstinate vesical affection, the results were far from being satisfactory; but in the remaining twenty-seven the treatment proved highly successful. In eighteen of the twenty-seven complete cure ensued (and that in eleven from the bougies alone, and in seven from the bougies and astringent means). In nine a considerable improvement was obtained; in fact, the only symptom left was a scanty mucoid discharge recurring from time to time. In relatively recent or mild cases from four to six sittings proved to be sufficient for effecting cure. In a majority of cases, however, a one- or two-month's course was necessary for the purpose, while in some unusually severe cases where a relapse took place another similar course was to be repeated some months later.

The same method (in the shape of the insertion of Nos. 20 to 25) gave also most gratifying results in eight cases of sexual astenia with spermatorrhœa and (incomplete) sexual impotence.

Dr. Szadek arrives at the following general conclusions: 1. The method under consideration proves very useful (*a*) in many cases of neurasthenic irritation of the urethral mucous membrane; (*b*) in many cases of inveterate gleet, especially in those characterised by infiltration and other morbid changes in the mucous membrane and submucous tissues. 2. It proves beneficial, further, in inveterate gleet of an atonic origin, or in that kept up by local nervous disturbances. 3. In some cases, however, the mechanical treatment must be supplemented by a subsequent course of local astringent remedies. 4. The method is free from any untoward accessory effects, provided it is practised with due precautions (including antiseptics).

On Obtaining the Duodenal Juice from Man.—In the *Correspondenz. Blatt fuer Schweizer Aerzte*, No. 6, 1889, p. 161, Dr. B. Tchlenoff, a *Volontairassistent* to Professor H. Sahli's clinic, in Berne, says that the perusal of Dr. Boas's paper (*Centralblatt fuer Klinische Medicin*, No. 6, 1889) has induced him to undertake a course of experiments with obtaining the duodenal juice after the plan given by the said German author. The method consists (*a*) in a preparatory washing out the patient's stomach with one and a half litre of a one-per-cent. solution of soda; (*b*) introducing a gastric tube into the organ; and (*c*) a light massage of the epigastrium, in the direction from the right lobe of the liver towards the pylorus (in order to open the latter and to force out the duodenal contents into the stomach). The experiments were carried out by Dr. Tchlenoff in seven patients suffering from atrophy of the gastric mucous membrane, dilatation of the stomach, stenosis of the gullet about the cardia, etc. In five of the seven the attempts proved successful; that is, the author succeeded to obtain from ten to seventy cubic centimètres of a fluid which possessed a high power of dissolving fibrine and transforming starch into erythrodextrine and dextrine. The fluid had either an alkaline reaction (in three cases) or a faint acid one (in two), and was either colourless (in three) or greenish (in two).

To judge from Drs. Boas's and Tchlenoff's experiments: 1. The duodenum contains a comparatively considerable amount of the pancreatic juice and bile even during the patient's fasting (Boas says that in twenty persons he experimented upon he was able to extract from eighteen to two hundred cubic centimètres of the juice, the average quantity attained being about fifty cubic centimètres). 2. A greenish-tinted fluid often found in an empty stomach of patients suffering from various gastric diseases undoubtedly contains bile penetrating into the organ from the duodenum. 3. The enteric juice retains a high digestive power even when the gastric one loses the latter entirely (as has been the case in three out of five patients of Dr. Tchlenoff).

The latter circumstance presents a considerable practical interest. The question naturally arises whether, in cases of atrophy of the gastric mucous membranes, would it not be more rational to prescribe a liberal mixed dietary, in the expectation that all kinds of food ingredients—proteids, starch, fats—would be duly digested by the pancreatic juice? To assist the intestinal digestion the (atrophic) stomach might "be transformed into a kind of a duodenum—that is, the pancreatic ferments, with addition of some alkalies, might be administered."

[The internal administration of a 12 to 15 per cent. pancreatic infusion, or of a good pancreatine, is successfully resorted to in cases of gastric atrophy by Dr. Reichmann, of Warsaw. *Vide* the *Wiadomoski Lekarskie*, October, 1888, p. 125.—Reporter.]

V.—HASTINGS HEALTH MEETING.

SPECIAL PAPERS.

1. Educational Overstrain—Overwork in Schools—Defective Eyesight.—At the meeting in the large hall on Thursday, May 2, Dr. Humphreys read a paper with the above title. Dr. Richardson presided, and, opening the proceedings, said they were disappointed in the absence of Lord Brassey, who was detained abroad. A telegram he had sent stated that he was on his way, but had only reached Gibraltar. They were deeply indebted to Dr. Humphreys, who had kindly come forward, and at the last moment, to fill a gap, had extended his paper.

Dr. Humphreys said Lord Brassey had done much for education by building the School of Art, and then he filled the library, and afterwards generously handed over the building to the town. Continuing, he said education was the drawing out of the mental, physical, and moral qualities. There was a close parallel between the brain and the body. The brain was a wonderful organ, and in development very slow; from observations in the dead mind they saw its growth and judged its composition. All that modern science had given them did not tell them what mind was. It must be judged by observation. When the weight of the brain was less than thirty ounces, ordinary human intelligence was impossible. Some persons went to forty-nine, and Cuvier to sixty-four. In idiots it was sometimes as low as eleven. At birth it was about fourteen. Man reached his maximum power generally at about thirty-five, but women younger. The mind, like the body, could be overstrained. The study of it seemed yet to be in its infancy, though it had been so long carried on. He would endeavour to indicate the remedies for overstrain, and its cause. Even in Roman times there were evidences of overstraining of the mind. Sir Crichton Browne had, in recent years, brought out an able report on overstraining in public elementary schools, and found 46 per cent. suffered from headache, talking in the sleep, and those were probably but indications of worse disorder. Increase in the number of suicides was suggested as an outcome of the overstrain. Dull children under it seemed to become duller and less intelligent. The report was severely criticised in official circles, but undoubtedly, there was much truth in what was said. Bad eye-sight among the children of the poor became more common, and such was found to be the case in Germany. Short-sight, a great oculist said, was also probably due to other causes as well. Another oculist said in a few generations probably all dwellers in towns would be short-sighted. It varied in the schools according to their situation. In bright buildings, with open spaces in front, it was not so bad as in dark buildings in narrow thoroughfares. Mr. St. Clair Buxton had written to the *Standard* on his experiences in connection with bad sight at an ophthalmic hospital, saying it was, in his opinion, partly, at any rate, due to over-study, and he had grave doubts for the future. Many children, he said, were punished for backwardness, when it was only due to short sight. "Surely," he added, "if Government compelled children to go to school and use their eyes, those boys and girls should be examined ophthalmically." Proceeding, Dr. Humphreys spoke of a case of a boy who had worked hard, and who was unwell from overwork. He was sent to prepare for the Navy, and was very clever. He worked hard, and it was found his sight was failing. Care was not taken, however, over the sight for some time, till it became most serious. Total rest was ordered early in the present year, and he improved, but his sight was very bad at the present time. It showed the first warnings of defective sight must not be ignored, and it showed if such care was not taken how long it would be before a cure could be effected. Dr. Humphreys having explained the manner in which the nerves and organs of the eye were affected by overstrain, went on to give the case of a girl in a high school who had been overworking, and who had had to rest for several weeks. Severe headaches, accompanied by vomiting, was brought on in some cases. When the growth was rapid, care should be taken to avoid over-study. Did modern education tend to make children more clever or more stupid? Reasonable training was good for the brain, as was exercise for the muscles. The kinder-garten system seemed to be an admirable one, but at present had only been adopted for the younger children. After quoting Ruskin, showing the fallacy of supposing that noble language was an ignoble trick of grammar, and which he characterised as one of the chief services of education, Dr. Humphreys went on to say that Ruskin said the moderns learnt to paint by drawing by painting first. It was said the fineness of Italian sculpture was often due to the great fineness and delicacy of the goldsmith's work. By faulty education, boys and girls were taught to dislike learning instead of to love it, and abandoned it when they left school. But the reverse should be the case. In former years, at Hastings, the Mechanics' Institute taught some useful matter, but that association had passed away, and now newspapers and political meetings seemed sufficient. He hoped it was not so elsewhere. Children were taught dates, and the kings and queens of England, and their children, but not to understand the real meaning of it all. A person who shortened the hours of school would be doing a good service, and Sir E. Chadwick had rendered valuable service by securing the half-time system for children engaged in factories. Turning to handicraft instruction, he showed that the Jews of old paid much attention to the matter. Some great scientists had been mechanics in their younger days. A system of handicraft for the schools was introduced with great success in Sweden and Norway. He referred to the

Slojd system. It was taken up in other countries, but England was slow to adopt it. In trade, masters preferred to take as apprentices lads who had passed through the system. Schools were not the place for education that should be learnt by apprenticeship, or at colleges, but the foundation work might be laid at the schools. Something of cookery should be taught to girls in schools, but he hoped the cookery reformers would be able to dispense with that, and teach it in the homes. Sanitation had to do with the mind as well as the body. No satisfactory substitute had been provided for competitive examination. He did not see why a test could not be provided which should ascertain what there was in a candidate without that candidate being crammed. To bring about the desired ends, they must work and despair not.—The address was listened to with great attention, and Dr. Humphreys was warmly applauded at the close.

Sir E. CHADWICK said in Germany he had seen the Forces, and generally one-third of them were spectacled. He thought one remedy was to reduce the length of the sustained attention and study. If attention was not sustained by interest in the subject, the time was wasted. He thought three hours might be the limit of compulsory attention in elementary schools. He had asked pupil teachers how many of their children could give attention for more than three hours, and they said one-third. The children forgot a large proportion of what was taught them, and in ordinary conversation and occupation forgot the instruction they had received.

Dr. COOK moved a vote of thanks to Dr. Humphreys for his paper, which he said was very instructive, and well worthy of consideration. The first step in a young child's education had to be taken up from the cradle.

Dr. BENDER seconded the motion, and said the ancient Jews, however learned they were, always knew a trade. He could fully bear out Dr. Humphrey's remarks, and, as German-born, he could say that his bad sight was due to the bad paper on which the German books were published, and the difficult type.

2. Women's Work in Sanitation.—A paper on the above subject was presented by the Lady Mount Temple and the committee of the Ladies' Sanitary Association. They said they presented the following details of the work of the Association in response to the request of the President. Women's work in life was preeminently to influence for good. That they could exercise that power is simple womanly fashion, and help men to promote sanitary reform, was the belief which induced a few earnest-minded women, in 1857, to form a society, whose aim should be to popularise and extend sanitary knowledge among all classes, but especially among the poor. This they endeavoured to do by publishing various tracts. The titles sufficed to show the prevalance of an idea that a wide-spread ignorance existed concerning the laws of health, and that much of the debility, disease, and premature mortality in the country could be prevented. It was not easy to take up the sanitary crusade against dirt and disease, even so recently as thirty-four years ago; health was not then the fashionable topic of conversation. Health Congresses were unknown then. Medical men and other advanced sanitarians, realising the assistance women could give in extending sanitary teaching, were ready to help, and the publication sold freely. Masses of sanitary instruction were issued from the Press. The Women's Association might claim to have been a pioneer in the new department of literature. Many of the publications had been translated into other languages, and bound up with religious and other tracts. It was a curious and significant fact that the sanitary tracts were always the shabbiest when returned. With an average yearly income of £350, the Ladies' Sanitary Association had issued over 2,000,000 of sanitary tracts, and delivered hundreds of lectures, formed Branch Associations, started a Destitute Children's Dinner Society, and weekly outings for poor children to the public parks, and arranged depôts for the loan of cleaning materials. It had encouraged window gardening, outdoor recreations, gymnastics, and swimming. Among various things exhibited at the Office, 22, Berner's-street, Oxford-street, was "Corn Coffee," which might prove the coming desideratum as a wholesome refreshing temperance beverage. Seats in shops for tired *employes*, and the Early closing movement had been assisted. It was only necessary to refer to the efforts of the Ladies' Useful Work Association in Birmingham, and the Yorkshire Ladies' Council of Education in Leeds, to prove that groups of women had been working zealously for years in large towns and villages. By the ready testimony of Corporations and Medical Officers of Health, those feminine efforts had proved acceptable and influential for good to the community. Florence Nightingale and Miss Ryland had proved how women could help men in sanitary work. In the battle undertaken against dirt, disease, unthrift, and intemperance, women had not shrunk from the responsibility of bringing unsavoury facts and insanitary conditions before the authorities who could redress such evils. There existed grave sanitary moral questions in which women felt the deepest interest, and in the solution of which they hoped to share. As a rule, women wished to do thoroughly and promptly what they undertook, and were, perhaps, the less tolerant of vested interests, licenses, bye-laws and regulations, lack of precedents, etc. They cordially welcomed all that might serve to develop home and home life for the people. They were, happily, enlarging opportunities of acquiring the training needful to make women the efficient helpers they would gladly be to those who were marching with themselves along the arduous path of life. In prisons, reformatories, infirmaries, asylums, and educational establishments there was scope for women's work. Looking around, therefore, from the stand-point that the past experience of the Ladies' Sanitary Association yielded, of what women had been able to do, and realising thankfully the increased opportunities the present time afforded for training them for proper work, it might be assumed that women, having done what they could to help men in promoting sanitary reform, would continue to do so, and, with increased light shining more clearly, go on in the matter of duty, and become yearly better help-mates for men.

Dr. HUMPHREYS, in remarking upon the paper, announced that Lady Mount Temple was prevented from attending by bereavement, and bore testimony to the large amount of good done by the Ladies' Sanitary Association in checking the spread of infectious diseases.

3. Sanitary Legislation—Pure Air and Water—Healthy Homes—Overcrowding.—Mr. WILSON NOBLE, M.P., said that sanitary legislation was at once the most ancient and most recent. After speaking of the Jews, he continued as follows: Within what may be called, comparatively speaking, modern times, we find death prowling through our crowded cities, and even our country lanes, striking down with one hand the strong man in the prime of life, and with the other the woman and her little child, unchecked and unheeded, because the people did not know the cause of his coming, and, consequently, were unable to take precautions against his ravages. We have to ask if we are making progress? A few figures will, I think, show we are. The death-rate per thousand in the years 1660-79 amounted to 80 (plague and fire); 1681-90, 42.1; 1746-55, 35.5; 1846-55, 24.9; 1871, 22.6; 1887, 18.8. In London, in spite of its size and densely-packed population, the death-rate is only 19.6. It is to the present century that we must look before we find any serious steps being taken on the part of the Legislature to insist upon more sanitary conditions being established. It is not my intention to recommend any particular legislation, because I do not wish to enter upon any matter of a controversial nature, as the President's addresses at this Congress are not subject to discussion. I think I shall better fulfil the duty which I have been called upon to undertake if I limit my remarks to a brief historical summary of past and present legislation, considering the defects in our present system, and enquire how far it is possible to remedy them. Now the

CHIEF REQUIREMENTS OF HEALTH

are: (1) Water supply, pure and plentiful; (2) fresh air circulated by ventilation; (3) removal of sewage by adequate drainage; (4) general cleanliness. How far have these been insured by legislation, and can we look to legislation to insure them in the future? Before you can expect Parliament to move in the matter, you must show that these things are necessary. The great obstacles to sanitary improvements are ignorance and poverty. I do not mean to imply that these are synonymous terms, so as to make them to appear as one cause, but as two entirely distinct causes of insanitation. In other words, I do not mean to imply that the poor are necessarily ignorant. As to the removal of the first of these obstacles—ignorance—it is being rapidly dissipated. We have fortunately within our midst many men who have devoted their lives to sanitary science—men who are daily educating us and showing us how we may make our towns healthier, and our houses more wholesome; and consequently how we can prolong our lives, and protect ourselves against sickness and disease. These men are striving to attain a definite goal—the amelioration of the mental and physical condition of mankind. At present the death-rate throughout England is 18.8 per 1,000. Looking back a hundred years this is a very considerable reduction. Though we have been able in the last two decades to reduce the death-rate about 4 per 1,000, this reduction implies a greater progress than the figures will at first sight warrant. It shows that we possess a greater power of contending with the forces of disease than we had in the past, because the natural causes of insanitation are on the decrease. There is a strong tendency for people to congregate in towns, owing to the necessity of finding work. If people having reached the towns were able to find clean, healthy, and roomy dwellings, the result would not be so detrimental to health, as it is not the size of the town which produces insanitary conditions, but the destiny with which the population is packed. If, therefore, we could increase the areas of towns in proportion to the increase of population, we should very materially reduce the tendency

to sickness, and consequently the death-rate. But, unfortunately, the bulk of the people who flock into the towns go there for the purpose of obtaining work, and must live near their work, consequently producing all the

EVILS OF OVERCROWDING,

about which I shall have something to say presently. Therefore, though the death-rate throughout England continues slowly to decrease, yet the progress of sanitary science is rapid; though the workers are few, yet are they earnest and energetic. They are daily acquiring knowledge, enabling them to cope with the ever-growing causes of disease, and they as rapidly distribute it; and if more towns were to hold congresses similar to this, where the people would have the advantage of learning what is necessary to the requirements of health, and, at the same time, instructing us who are in Parliament, and showing us where our responsibility lies, we should more rapidly reach the haven for which we are steering. This can, however, only be done by perseverance and patient labour, by allowing no prejudices to interfere with progress, but by believing that those who have devoted their lives to a particular science must at least know as much about it as those who have persistently ignored it. So much for the removal of ignorance, which, I trust and believe, is but a matter of time. As to poverty, that cannot be so readily removed; the poor we have always with us, and always shall have. So we must endeavour to ameliorate their conditiou. They are largest in numbers, and consequently the greatest sufferers, and all surrounded by more uuhealthy conditions. It is true that at one time there were advocates of the Malthusian theory—by which it was hoped that death from disease would remove the surplus population in overcrowded district—I say "were" because I believe very few of its advocates exist at the present day. Pestilence as a check on population has now been proved to be no check at all, for, instead of reducing population, it merely leaves it more sickly and enfeebled. In unhealthy localites, such as the slums of London, where epidemics run wild, the usual interval between births is one year, against two years in the more healthy agricultural districts, owing, no doubt, to the fact that in the latter case the mothers nurse their own children, and in the former they do not. This increase in the birth-rate, therefore, compensates for the increase in the death-rate, the net result being that the unhealthy condition of a locality does not reduce the population. I am inclined to regard the

DWELLINGS OF THE POOR

as one of the burning questions of the day, and one which demands our serious consideration, both on account of its importance, not to the poor alone, but to the whole community, and because it is, at the same time, one most difficult to solve. Those who have studied the report of the Royal Commission on the Housing of the Working Classes will, I think, wonder, not at the high rate of mortality in our large towns, but at the comparatively low rate, considering the awful condition in which some of our people live. Lord Shaftesbury, who spoke with sixty years' experience, said that however much the condition of the poor had been ameliorated in other respects, the over-crowding was becoming more serious than ever. In some of the central parts of London, as in the neighbourhood of St. Pancras, over-crowding had not increased, simply because the locality was so full that it could hold no more. In many parts it is unusual to find a family occupying more than one room. Until the report of the Commission was published, very few people had any idea of what was taking place within a mile of their own doors. In one case we find a family of nine persons, five of whom are grown up, occupying a room 10ft. + 8ft.; two families in one room 12ft. + 8ft.; seven persons in a room 12ft. + 6ft., and only 7ft. high; a father and mother are found occupying a room 10ft. + 5ft., with four children. Over-crowding also exists in provincial towns, and though in some places extremely bad, cannot compare with London in its worst parts. In Newcastle-on-Tyne, 140 families were found in 34 houses, each consisting of four rooms and two cellars. In another case 50 houses with 230 families; and in another, 62 houses, 310 families. Instances are given at Camborne, in Cornwall, where seven, eight, nine, and even ten and eleven persons were found living and sleeping in one room. In Birmingham, another kind of over-crowding was noticed before the improvement schemes were carried out; that is to say, of crowding a large number of houses on to a limited area, the rooms of the houses not being occupied by excessive numbers of persons. Over-crowding is invariably accompanied by many other evils, injurious alike to health and mortality, such as structural defects, bad drainage, and bad ventilation; but setting these aside for a moment, over-crowding has been found to be injurious in itself. Sir Edwin Chadwick has shown that there was an excessive death-rate in single room tenements, a lower death-rate in double room tenements, and a still lower rate in three roomed tenements. In parts of London it was found that even where there was no outbreak of epidemic the death-rate in one case was 44·4, another 53·7, and in another as much as 70·1 per 1,000. As has been pointed out, over-crowding is an ever growing evil, because the causes which produce it are ever on the increase, and themselves are productive of fresh causes. We have first the

GENERAL MIGRATORY TENDENCY

towards the towns. The workman, having reached the town, is compelled to be as near as possible to his work, or if not in regular employ, to be in such a neighbourhood that he could readily get to work should any offer itself. Sometimes work may be obtained provided the workman can get to it by six o'clock the next morning. A colony of poor beings thus formed, it is necessary to feed them. The usual shops are too expensive, by degrees are closed, and become occupied by other families, and costermongers supply the necessaries of life more cheaply than the shopkeepers, and in their turn add to the evils of overcrowding, for they are bound to live near the place where they find a ready market for their goods. Then the houses become old and dilapidated and have to be removed. A street improvement scheme is floated, and scores of homes are demolished—not one moment too soon—but, unfortunately, while the new homes are building and the streets being opened, the poor are still more densely packed in the remaining houses. Though the building improvements, no doubt, confer inestimable benefit on the locality at large, yet while they are in course of progress, they inflict most cruel hardships on the poor in the immediate neighbourhood. Nor is this the whole of the evil. The dwellers in these crowded parts become enfeebled by sickness and their poisonous surroundings, and are unable to do the same amount of work as they could do when they first came to town. The contractors consequently advertise for men from the country, who, fancying that the demand for labour is greater than the supply, flock up to town with their families to obtain work, thus adding to the already too dense population, and in their turn becoming sickly and feeble, only to be replaced again by fresh supplies from the country. The people being obliged to live near their work, they are compelled to pay almost any rent demanded, and this precludes the possibility of their occupying in many cases more than one room. The rents, too, are increased by the middle men, the freeholder having in many cases but slight direct interest in the welfare of the occupiers. He usually inserts clauses in the lease compelling the tenant to keep the house in repair, but he often is unable to insist upon these repairs being carried out, because he knows that if he did, the already exorbitant rent charged by the middle man would be still further increased. That the rents charged are exorbitant may be seen from the fact that some of the middle men, or house jobbers, as they are called, obtain as much as 150 per cent. profit. I do not wish to discuss the breaking up of the large estates, which is advocated by some as a remedy for these evils, because the question of the

ENFRANCHISEMENT OF LEASEHOLDS

is a current political topic. I think, however, it should not be forgotten that someone would have to be landlord, the poor being unable in most cases to own their own houses, and it is a question whether overcrowding would be reduced by replacing the large landlords by the present middlemen. Among the accompanying evils of overcrowding may be mentioned insufficient water supply, bad drainage, bad ventilation, and structural defects. In many of the large tenement houses there is a single water supply, which, not being constant, is drawn off at certain hours of the day, and kept in tubs in the sleeping rooms; or if there is a cistern it is often outside in the sun, and uncovered. Those who travel in town may often have noticed the open cisterns in summer covered with green growth of rank water slime, which, if examined even in the most careless manner, would be found to be teeming with animal life. This water, when it holds out, is used for drinking and all domestic purposes. One very necessary reform I hope we may shortly see carried out is the purchase by the localities, metropolitan and provincial, of all water companies, a constant supply being enforced, thus abolishing cisterns, which are more often traps to catch any passing disease than containers of pure and wholesome water. But the water supplied must be pure and wholesome, for there is no more ready vehicle of disease than water. It has been shown, over and over again, how epidemics have arisen from contaminated water. Very frequently it is drawn from a well near a leaky cesspool or drain. Persons have taken typhoid fever when contaminated water has been used for washing milk cans. As water is such a willing carrier of disease, the fact should be utilized for our advantage, and not to our destruction. As science grows, our power, not of controlling, but of utilizing the laws of Nature, increases. Our present knowledge enables us to use it to our advantage by conveying all impurities from our houses; and yet, for the most part, we only allow it to bring them to us. It is within our power to obtain pure water. Let us have enough of it to carry off to the sea, or into the porous earth, which is an equally effective purifier, all our refuse and dirt. But the source of water must be plentiful and

pure. Nature grants us this, but again we have abused her gifts. Look at our great rivers, and contemplate what they were and what we have made them. We have means to-day of distributing sewage over the face of the earth, where it was by Nature intended to be placed to nourish and improve the growth of the plants we require. Instead of this, we pour it into our rivers, where it is washed backwards and forwards by the tide, contaminating the water, and not only making it absolutely unfit for use, but converting the river itself into an open cesspool. I venture to think that there are many less useful questions brought before Parliament than that of the disposal of sewage and the

PURIFICATION OF RIVERS.

Air, as well as water, is essential to the well-being of the community, but the air must circulate, or it soon ceases to be pure. It is, however, not my province to dwell upon any particular method of ventilation even were I competent to do so, except so far as the action of the Legislative may prevent or assist the access of air to dwellings. Air is the common property of mankind, and no one should be allowed to deprive his neighbour of it by the erection of buildings in such a manner as to cut off the supply. By the Buildings Acts every house is obliged to have a certain amount of air space back and front, but in many cases these regulations are wholly disregarded. Houses are built back to back, or are separated by narrow alleys, the centre of which is often little better than an open drain into which the filth from the houses is thrown, contaminating the air before it reaches the windows. Air, like water, is a great destroyer of impurities, and consequently a powerful deodoriser. I remember an old friend of mine in the medical profession saying that the chief use in disinfectants was that they made such a smell in the room as to compel persons to open their windows and admit fresh air. Structural defects, too, are often the cause of much sickness. It too often happens that houses are built of the commonest materials, and put together with the worst workmanship. The drains very shortly become leaky and dangerous, and the houses, even were they not overcrowded, would be wholly unfit for habitation. Mr. Wilson Noble here took a brief survey of past and present legislation, and then continued: The law, therefore, seems tolerably satisfactory if we regard its provisions and not its results. But it is to the results that we must look, and if we ask why they are not more satisfactory, we shall find that one reason is the indifference on the part of the inhabitants to the requirements of sanitary regulations. But in the more crowded towns, both metropolitan and provincial, there exists one great difficulty. If you provide the people with a sufficient number of rooms to meet the

REQUIREMENTS OF DECENCY AND HEALTH,

and if these dwellings are provided with the necessary sanitary conveniences—if, too, they are to be built in such a manner as to ensure perfect ventilation, and prevent over-crowding, one of two things must result. Either the occupier must pay more rent, or the builder or landlord, as the case may be, must forego his interest on his outlay. If the latter, the result will be that the houses are not built at all. On the other hand, can the working classes afford to pay more than they do at present? Under the present conditions, I think not; but under other circumstances, I think they can. We have already seen what an exorbitant profit the middlemen sometimes make. You can, therefore, do away with him, or place under such stringent regulations as to prevent him letting lodgings in an improper condition. You cannot pass an Act of Parliament to say what rent a man shall pay, but you can enact that men shall not pay rent for dwellings that are unfit for habitation. We will suppose, then, that by means of legislation and inspection, we have places that are fit homes for the working-man. Can he afford to pay such rent as will give a fair return on the outlay, even though it should be higher than is at present paid? If we consider what he gains in return, we shall see that he can. Over-crowding and unhealthy dwellings produce debility, weakness, and exhaustion, rendering the poor particularly subject to sickness and disease. It has been found that at the lowest estimation every workman loses 20 days in the course of the year from exhaustion alone. Not only do those surroundings deprive a man of a certain number of working days, but they of necessity shorten his life. If, therefore, you can give a man such a home as to prolong the average span of life, you are surely giving him something that will be worth paying for. Not only does he gain strength, enabling him to work a larger number of days in the year, and so earn more wages, but you are also adding to the number of years during which he can work; and as you reduce the likelihood of premature death, so you reduce the premium of insurance. There are many items, therefore, in a poor man's expenditure which might most advantageously be devoted to a higher rent without increasing his expenditure as a whole. It may be said, and with great justice, that a working-man who is in regular employ might regard a higher rent for better dwellings as a good investment, but there are thousands below the regular wage-earner who have nothing to invest, and who cannot pay increased rent, no matter what advantages they may gain in doing so—in fact, often he can pay no rent at all. It is here where the real difficulty lies; and the question remains: to what extent are the Government called upon to find homes for these people? After expressing his opinion that it unwise to provide buildings out of the rates, he said: I do think some steps might be taken by Municipal or County authorities, backed up by an Act of the Legislature, if possible to invest money in the

THOROUGH SANITATION OF ROOKERIES

and other places where over-crowding and its unhealthy surroundings become a danger to the community at large. If I regard this for a moment from a monetary point of view, as I have done in the case of the individual, it is not because I consider this its most important aspect, but I do so, first, because the advantages of promoting the health of the body politic are so obvious as not to need insisting upon, and to prove, if possible, to those who might object to any increased outlay of public funds, that they are not wasting their money, but investing it to a good purpose; that, though they may appear to be casting their bread upon the waters, they will inevitably gather it again where they least expect it. It should, however, not be forgotten, as I have already pointed out, that County Councils have the power of erecting and controlling labourers' dwellings, charging such a rent as will give a fair return; but the enormous cost to them and the Trustees of the Peabody fund have hitherto greatly checked their undertakings. It is very desirable that public bodies should be encouraged to build as much as possible, as they are naturally satisfied with a smaller return than a contractor who builds solely for profit. I have it on the authority of my friend, Sir Lyon Playfair, that there are every year 125,000 deaths in this country from preventible cases. The investigations of Pettenkoffer have shown that there are 39 cases of serious sickness for every death, therefore we have annually four and a quarter million cases of preventible sickness, and as these cases last on the average 18½ days, irrespective of the 20 days mentioned before, we lose annually more than 78½ million days' labour, which, at 2s. a day, represents a loss of over 7¾ millions sterling. Surely, therefore, putting it on its lowest ground, it would be an economy to adopt sanitary measures, and an excellent investment for the localities to make. It is open to doubt whether you can appraise at any money value the life of an individual, but you may fairly compute money which will be saved by a proper outlay for sanitary purposes. To show what has been done in the way of saving life where sanitary improvements have been undertaken, I may mention that after the defects in the sewage of Salisbury had been remedied, the deaths from phthisis fell forty-nine per cent.; at Ely, forty-seven per cent.; Rugby, forty-three per cent.; and Banbury, forty-one per cent. What we also want is a thorough and efficient

INSPECTION OF DWELLINGS

and localities which are in an insanitary condition. I have endeavoured to point out that the legislation is satisfactory, but that where it breaks down is in the want of knowledge obtainable. I know that too close inspection is repugnant to our feelings, but we often have to submit to things we dislike for the public good, and you can only remedy sanitary defects when you have knowledge of them, and this knowledge can only be obtained like other knowledge, by seeking it. We are often told the Imperial Parliament is omnipotent, and can pass what measures it will. But there is in existence a code of laws which are older than the Parliament itself, which are most immutable than those of the Medes and Persians, and which are inexorable in their execution, and which are enforced by the terrible sanction of sickness and death. These are the laws of nature. You may make what regulations you like by means of your Imperial Parliament, but unless they are done in accordance with the laws of nature, they are worse than useless. Nature is not a hard task-master, because her ways are clear and well defined. She does not act in one way to-day, and in another to-morrow. You may repose the fullest reliance in her promises, knowing full well that as she has acted on occasion, so she will act again under similar circumstances. Some of these laws are known to us, others have as yet to be discovered, but are daily being revealed and placed at our disposal. We cannot always act in accordance with laws that we do not know, but do we always obey those which we do know? If we did, we should be relieved of much sickness, and its accompanying misery. It might be thought from what I have said that it would be useless to pass any measures of sanitary legislation, for nature will have her way in spite of you. If these measures were conceived in a spirit of antagonism to nature, they would be useless, or worse than useless, and you may depend upon it that where pestilence has visited a locality, or where there has been an abnormally high death-rate, it will be found that Nature's laws have been disobeyed. If, therefore, your legislation is to be of any avail, it must have for its object the utilisation of Nature's forces. There are constantly moving about in our atmosphere myriads

of disease germs, seeking, as it were, places where they can obtain a foothold. If our homes are clean and well ventilated, they will pass harmlessly by, but if they find any decaying matter upon which they can settle, they will certainly do so, and we pay the penalty. Let us, therefore, once and for all recognise the vital importance of living in a perfectly sanitary condition. We may be able to a certain extent to bring it about by legislation, but legislation is no use unless it is enthusiastically and intelligently carried into effect by the people it is intended to benefit. Whatever this legislation be, let it follow, and not seek to drive the forces of Nature. When we have done this we shall reap our reward increased comfort, a diminution of sickness and disease, and a lowering of the national death-rate. We shall obtain blessing greater even that prolongation of life, which, without health, is often a curse rather than blessing. Give a man health, and you give him something more to be desired even than length of days. You give him that which alone makes life enjoyable or even bearable—you give him contentment and happiness.

Nor love, nor honour, wealth, nor power
Can give the heart a cheerful hour
When health is lost. Be timely wise;
With health all taste of pleasure flies.

The Spirit of the Societies.

CLINICAL SOCIETY OF LONDON (Christopher Heath, F.R.C.S., president). **Hemiotrophy of the Tongue.**—This case was shown by Dr. THOMAS BARLOW, and associated with it was cervical spinal disease. The patient was a child who some two years before had been pitched off a barrow on to the top of the head; there appeared to be some peripheral paralysis, as evidenced by difficulty in swallowing, etc. This had been followed by atrophy of the right half of the tongue.

Disease of the Middle Ear, complicated by Suppuration in its Vicinity.—Mr. ARBUTHNOT LANE read brief notes of these cases, which had been under his care during the last few months, and the complication had differed in each case. He considered the risks involved in operative interference were very slight, and in doubtful cases the middle ear and its vicinity should be thoroughly explored.

Case 1.—A woman, æt. thirty-one, had, on August 21st, "ricked" her neck. She felt at the time as if something had given way in her right ear, which up to that time had caused her no trouble whatever. At the same time she noticed that pus was gradually escaping from the meatus. She was then affected with headache, gradually increasing in intensity in the right half of the head, with pain beneath the upper half of the sterno mastoid. Mr. Lane saw her on September 5th. Pus welled out freely from an aperture in the membrana tympani. The right ear was quite deaf. There was a tender and painful swelling beneath the upper half of the sterno mastoid. There was no optic neuritis. The mastoid cells were freely opened with a gorge, and were found to contain offensive pus, and a channel was cut into the middle ear, from which pus and caseous material were removed. A metal drain was fixed in the middle ear, and that cavity irrigated daily. On August 2nd an abscess, beneath the sterno mastoid, was opened, and a probe could be introduced through it into the mastoid process. The patient was now in excellent health.

Case 2.—A girl, æt. twelve and a half years, admitted into Guy's Hospital, under the care of Mr. Horne, on September 18th, 1888. In August, 1887, an abscess had formed in her right ear, and was well in a short time. She had no further trouble until fifteen days before admission, when she was attacked with great pain and swelling about the same ear. On admission, there was a large swelling, and a copious discharge from the meatus. This abscess was freely incised and irrigated, and was found to communicate through the meatus, between the cartilage and bone, with the middle ear. After this the child lost all pain, and went on well till September 23rd, when she became drowsy in the morning. The drowsiness increased during the day, the pupils dilated, and the child vomited. At 10-45 Mr. Lane saw the child in Mr. Horne's absence. The respirations were then extremely slow, the child was unconscious; there was no optic neuritis. Considering that an abscess in the tempero-sphenoidal lobe had probably ruptured into the lateral ventricle, he proceeded to operate, and removed from the temporo-sphenoidal lobe a quantity of offensive pus and fluid. A drainage tube was inserted, and the cavity thoroughly irrigated. The respirations became gradually normal, aud the child flinched when hurt. The improvement, however, did not last long, and the child died. The *post-mortem* examination verified the diagnosis.

Case 3.—A girl, æt. twelve years, had caught cold; had always been healthy till September 13th, 1888; she then observed a purulent discharge from the right eye which ceased in a few days. On September 25th, when blowing her nose she felt something crack in it, and she complained of pain in the back of her head. The pain continued till October 4th, when Dr. Horne was called in and asked Mr. Lane to see her with him. They found no pain or swelling about the ear or mastoid process. Fœtid pus escaped through a hole in the membrane. There was double optic neuritis and retraction of the head. The right ear was quite deaf. She was admitted into Guy's that afternoon. An operation was performed, and the child progressed well till October 8th, when the temperature ran up to 106° at 2 p.m. The headache and drowsiness returned, and she died on October 13th. The *post-mortem* examination showed that the dura mater pressing against the walls of the abscess cavity had sloughed, and the arachnoid cavity below the tentorium was in communication with the cavity of the abscess and full of pus.

Case 4.—Was admitted under Dr. Percy, August 15th, 1888; he was eighteen months old, and had suffered from periodical attacks of discharge from the right ear, preceded by pain every two months. A polypus was removed in 1887. On his admission on August 15th; he was in a semi-comatose state. Both discs were swollen. Mr. Lane was asked to see the boy on August 18th, and opened the mastoid cells freely, but found no pus. August 17th; the boy was better in the morning, but became dull in the evening. In the evening he had a rigor. August 18th, another rigor occurred. Mr. Lane gouged away a further portion of the mastoid process, and opened up a small collection of very offensive pus, adjacent to the lateral sinus. The lateral sinus was cleared of its septic contents upwards till healthy clot was reached. The internal jugular vein was hid below the thrombus to prevent any escape of blood from the sinus, and the entrance of antiseptic agents or septic material. The boy recovered very rapidly, and left the hospital well, and has since continued in excellent health.

Case 5.—W. S——, æt. eight years; for three years and a half he suffered from attacks of earache and otorrhœa on the right side at intervals of two or three months. On October 17th, 1888, he was attacked with earache accompanied with pain and sickness. On December 23rd he had two rigors in the morning, and December 24th, having had two more he was admitted into hospital under Mr. Lane's care. Mr. Lane operated, and the child lost the headache immediately, but suffered from pains in the abdomen, and his motions were very loose and offensive. For two days his temperature was moderate, but the pain in the abdomen came on at intervals. The boy became rapidly worse, and died on January 6th. Multiple abscess were present in both lungs, and especially in the right one. —Mr. GODLEE asked Mr. Lane whether he thought it always wise to explore the groove of the lateral sinus in all cases of suppuration. Mr. Lane, in reply, said he had no difficulty in clearing out the lower part of the sinus.

* * * *

HUNTERIAN SOCIETY (R. Clement Lucas, B.S., F.R.C.S., president). **Rickets.**—Mr. BIDWELL showed (for the president) a typical case of rickets in a boy æt. three and a half years. The head was much enlarged, with depression over the fontanelles, which were closed. The prominence of the occipital region, the stumpy appearance, the contracted chest, with well-marked headed ribs, the elevation of the sternum, the prominence of the abdomen, with the enlargement of the liver and spleen, the bowing forwards and outwards of the femora and tibia, with marked cardosis and genu-varum, were all very characteristic. The child had never walked. It had been improperly fed, but no family history of rickets or syphilis was obtainable.

Salol as a Dressing.—Mr. CORNER exhibited several cases illustrative of the antiseptic power of salol (salicylate of phenol) as a dressing for wounds after the pads had been rendered aseptic by a one in twenty solution of carbolic acid. Salol has a pleasant odour, and could be used freely without fear of poisoning or irritating, and when dry formed a hard but friable surface. A case was shown when the wound was dressed with salol and left untouched for a month, and remained sweet.

BRITISH GYNÆCOLOGICAL SOCIETY. **Case of Ectopic Gestation.** —Dr. JOHNSON, of Calcutta, contributed the notes of a case of ectopic gestation in a woman, æt. thirty-two, who was admitted into the Calcutta Hospital on January 31st, 1889. She had been married twelve years, and had one child now living. She had puerperal fever after that labour, and had not been pregnant since. Menstruation has been regular up to three years ago; since that time the quantity has been less, and menstruation accompanied by bearing-down pains. The last period was September 22nd, 1888. On December 24th, while playing

tennis, she was seized with a sudden pain, and felt faint. She was put to bed, and a lump was noticed in the right lower abdomen. She recovered, and resumed her usual occupations, but on January 2nd she was again seized with a severe pain followed by retching. In the afternoon she became quite collapsed. On January 6th a sanguineous discharge supposed to be menstruation came on, and she passed a complete cast of the uterus, supposed to be the after-birth. She continued unwell for some time, but by the end of January she was free from pain. At that date a lump was found on the right tube, reaching to a finger's breadth above the umbilicus, and three or four inches across the os, was patulous, and the cervix soft. It was diagnosed to be a case of extra-uterine pregnancy at about the fifth month which had ruptured into the broad ligament. Owing to the patient's refusal the operation did not take place till February 8th. They removed a fœtus about seven to eight inches long. The patient was so exhausted by loss of blood that she eventually succumbed.—Dr. EDIS said that in all cases where the symptoms were sufficient to justify attention being directed to the patient the idea of extra-uterine gestation ought at once to be entertained before waiting for the patient to be collapsed.

Laparotomy for Tubal Disease.—Dr. E. SINCLAIR STEVENSON, of the Cape of Good Hope, contributed the notes of a case of tubal disease on which he had performed laparotomy. The patient was married, had had five children and one miscarriage. She had suffered for fourteen years from constant pelvic pain. Several times the pain had been so bad she was obliged to stop in bed two days. He found her to be suffering from disease of the right appendages, and advised operation. In December, 1888, he opened the peritoneal cavity, and removed the appendages. The patient recovered rapidly, and on the tenth day was practically well. Unfortunately, on the eleventh day vomiting set in with other symptoms of intestinal obstruction. As she appeared likely to die he re-opened the abdomen, and found the parts glued together, but the adhesions were easily broken down. The omentum was twisted ltke a rope. He remedied this, and washed out the cavity with corrosive sublimate. The patient made a good recovery. He pointed out that the obstruction was evidently due to the attachment of the omentum, and the case afforded a good example of the rapidity with which adhesions formed in peritonitis.—Dr. EDIS insisted upon the importance of covering the intestines with the omentum before closing the abdominal wound. Drs. Barnes, Bantock, Bedford, Fenwick also took part in the discussion.

* * * *

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM, May 2nd (David Little, vice-president, in the chair). **Transparent Cyst of the Iris.**—Dr. A. BENSON (Dublin) read an account of a transparent cyst of the iris occurring in a man æt. twenty. It had first shown itself about a year previously, then disappeared, and re-appeared again. It then grew rapidly, until it had filled three-fourths of the anterior chamber, at which size it remained stationary until it was removed by operation. The wound healed well. Photos were shown (before and after operation).

* * * *

WEST LONDON MEDICO-CHIRURGICAL SOCIETY (William Travers, M.D., president). **Case of Obscure Nervous Disease.**—Dr. CAMPBELL POPE showed a case of obscure nervous disease, characterised by hemianæsthesia and paræsthesia.—Mr. BALLANCE showed a child, æt. ten months, with a large nævus extending over the right half of the forehead and right upper eyelid, which had been treated by electrolysis. A slough had formed, but the child was doing will. Other cases were mentioned, the treatment discussed, and the use of electrolysis in avoiding any scar of a disfiguring character dwelt on.

Charcot's Disease.—Dr. KEETLEY showed a case of Charcot's disease.

Sarcoma of Anus.—Mr. SWINFORD EDWARDS showed a man æt. sixty-four, with a large anal growth. The growth was sessile, and completely obscured all view of the anus. Microscopic examination of a small portion of it showed it to be a mixed celled sarcoma. Mr. Edwards had been unable to find a report of a similar case.—After some remarks by Mr. S. Benton, Dr. ABRAHAM mentioned a specimen of sarcoma of the anus very like the present one, in the museum of the Royal College of Surgeons, Ireland. This case, and two others which he had microscopically examined, were all alluded to in Mr. Ball's work on Diseases of the Rectum.

Three Cases of Orbital Tumour.—Dr. RAMSAY read for Dr. Reid, Glasgow, the notes of three cases of tumour of the orbit. 1. Fibrous tumour, which occurred in a man æt. seventy-five, and after existing for seven months began rapidly to increase in size. It was successfully removed through an incision at the outer part of the upper lid. 2. Sarcoma of orbit in a man æt. thirty. The growth had been noticed for two years, and had given rise to a displacement of the eye-ball, and loss of vision in that eye. It was removed by dividing the upper lid vertically, near its centre, and dissecting down to the capsule of the growth. 3. Carcinoma of the orbit in a man æt. seventy-five. The removal of the growth was accomplished with great difficulty, in consequence of its deep attachments, and the necessity of preserving the eye-ball, the other eye being useless. Three or four months after the operation a secondary growth occurred in front of the ear, and from this severe hæmorrhage occurred. Death ensued ten months after the removal of the growth.

Adenoma of the Lachrymal Gland.—Dr. SIMEON SNELL, Sheffield, related two cases, and exhibited the specimens. The first occurred in a servant girl, æt. twenty-five, and was removed December 15th, 1887. Shortly before the sixteenth birthday the left eye was noticed to be larger looking than the right, and gradually became more so. At the time of operation the tumour was felt beneath the upper eyelid, the eyeball being displaced forwards, downwards, and outwards, but sight was unaffected. The growth was removed by dividing the external commissure, and then dissecting it out. The eyeball returned immediately to its normal position. The tumour was the size of a walnut, and flattened on two sides. The second case occurred in a child æt. eight months. A swelling beneath the left upper lid had been noticed when the child was a month old. On November 15th, 1888, a small freely movable tumour, the size of a bean, was easily removed.

* * * *

EDINBURGH MEDICO-CHIRURGICAL SOCIETY (Professor John Cheine, vice-president, in the chair). **Pleurisy.**—Dr. ALEXANDER JAMES read a very good paper on some points in the pathological physiology of pleurisy and pleuritic effusions. After a summary of the generally accepted views on the pathology of pleurisy, the question of locality was discussed. Primary iodopathic pleurisy was undoubtedly commonest towards the base, while secondary pleuritic conditions might occur at any point dependent on the nature of the primary lesion. The frequency of occurrence at the base had been explained on the ground that there the pleural surfaces were less protected by muscular covering than elsewhere. It was of extreme importance to remember as a casual factor, that at the base there was a much greater range of movement of the pleural surfaces. This had been experimentally shown by the making of "pleural windows;" with greater movement there was a greater likelihood of irritation. Once the irritation was present, the inflammation spread from point to point by a process of local infection. The effusion of fluid was also commonest at the base; but it should be recognised that in the absence of adhesions, the fluid did not stand at one uniform level, as in a jar, but the upper limit was curved from front to back.

THE HEALTH CONGRESS (HASTINGS, 1889.)

THE Congress was opened on Tuesday evening, April 30th, at the Royal Concert Hall, Dr. B. W. Richardson (president) being in the chair. He was supported by the leading sanitarians of the country. The chief business of the evening was the delivery, by Dr. Richardson, of his presidential address, "On the Health of the Mind," of which the following is a brief summary:

"He said he wanted to declare from the platform the mental side of sanitation, and to indicate that from the present time forward the health of the mind, not less than the health of the body, belonged to the true and earnest study of sanitary science. Speaking of mental purity, he observed that one primary truth, for example, at once came forth, that the mental food most early and most continuously supplied was that which, for health or disease, most potently affected the mental surface, and carved its place upon it. But the feeding of the mind governed the appetite of the mind, and by what the senses took in the health of the mind was good or bad, clean or unclean. Each sense made its own bed. Let the eye for long series of years take in no view save that which is squalid, and common, and impure, and by that custom the mind represents the fashion of what it sees. For art, for beauty, it would lose its primitive adaptability, whatever they might have been, and after a set time for attaining maturity will remain, in respect to purity of sight, a deformed mind, one that can at best only be partially and imperfectly improved. A mind so deformed was never in perfect health and strength. Why for it could the earnest sanitarian plead for open spaces, flowers, a clear sky, a clean street, an artistic dwelling, all that makes life strongest and happiest? Why, indeed? The difficulties sanitarians were compelled daily to meet in our work of reform lay, beyond any descriptions that could be given, in unhealthiness of mental visions. Every man and woman was, more than he or she thought, the reflex of the schoolroom. Let that room

be bright, cheerful, healthy, and life begins from a good mental starting-point. Let that room be dark, littery, melancholy, dirty, and the presage of life is injured from the starting-point. Sir Edwin Chadwick said that the physical condition of a whole nation might be told by a nose sufficiently critical. And the statement was true. Unfortunately, the sense of smell was not yet so freed from the odours of disease as to distinguish, with due refinement, where there was, and where was not, every hurtful thing that gives a venomous odour; but that want of refinement was due merely to absence of purity and to deficient knowledge of the odours that are injurious. The detective sense was blunted, and often so much blunted that the worst odours were unknown to the mind, and being unknown, allowed the causes of disease to enter without the vaguest suspicion of their presence. Further on, Dr. Richardson observed, suicide also has its season of height and decline, its maximum being reached in June, and its minimum in February, like a true epidemic; and again, he said men, knowing nothing of their own mental health, threw themselves into mental strifes and contentions for which they were as little mentally fitted as they were physically fitted to remove mountains. The man, with his animal life worn out by professional or business labours, determined to close his honourable career by undertaking senatorial duties, which called for mental animal work of giant power. Another, whose emotional mind—always the master of his intellectual part—had led him constantly into serious scrapes and difficulties, permitted himself to enter into contests in which the whole argument turns on sentiment, and breaks himself to pieces in the struggle. In conclusion, he observed that to neglect the mind was to neglect the body itself. We have been able only to give a few brief and dispointed extracts from a lengthy and most valuable paper, but we hope we have shown our readers how interesting it was.

At the close of the address, Mr. Wilson Noble moved, and Dr. Bagshawe seconded, a vote of thanks to Dr. Richardson, which was carried with loud acclamation. The President returned thanks, and after a few remarks in French by Dr. Santa, the meeting came to a close.

WEDNESDAY.

At the meeting on Wednesday, Mr. Wilson Noble, M.P., read a paper on "Sanitary Legislation," published in full at page 372.

Mr. Wilson Noble then took the chair, and Dr. Drysdale read a paper on "Legislation on the Agricultural Utilization of Sewage." Sir E. Chadwick and Dr. Pietra Santa spoke on the subject, and then Mr. W. Alexander, chairman of Council of Public Sanitary Inspectors, read a paper on "The Status of Sanitary Inspectors." Sir E. Chadwick and Earl Fortescue spoke, the latter referring to his experience as secretary of the Poor Law Board and chairman of a Board of Guardians. Mr. Mansell, on behalf of Mr. Haviland, author of "Geographical Maps of Diseases," read a paper on "A Plan for a Governmental Survey of Disease." Dr. Richardson warmly eulogised the paper, speaking of its immense value. Dr. Drysdale also spoke. Dr. Gray, on behalf of Dr. Green, superintendent County Asylum, Northampton, read an essay on "Hygiene of County Asylums for the Insane." On the motion of Mr. Noble, seconded by Professor Hughes, the discoverer of the microphone, a vote of thanks was passed to those who had read papers, and the Conference adjourned for luncheon. Upon re-assembling, Mr. Wilson Noble took the chair, and the first paper was presented by Sir Edwin Chadwick, K.C.B., upon "An Annual Census." This was read by Dr. Richardson. It contained suggestions for annual stock-taking and reports on them for economical and efficient administration by local authorities. With reference to the means of obtaining this annual report, the paper said the eligible course would be to select for the service that local officer, the exercise of whose functions occasions his visits to every house in the district. It proceeded to enumerate several, amongst whom the postman seemed the most approved. After the reading, the paper was commented upon by Mr. Washington Lyon, Dr. Drysdale, Dr. Greenhill, Dr. Bagshawe, Lord Fortescue, and Dr. Gray, all of whom were more or less in favour of the scheme. A resolution was then passed to the effect that the Congress was of opinion that it was most important for sanitation and other objects that an annual census be taken, and commending the matter to the notice of the Government. Mr. Wilson Noble consented to present it in the House of Commons, and Lord Fortescue in the House of Lords.

THURSDAY.

Thursday was a busy day, and it was only with difficulty that the programme could be got through. The first matter to deal with was the reading of a paper by Major-General Webber, who was a distinguished engineering officer in the Egyptian Campaign, on "Lighting in Relation to Health." He traced some experiments on growing plants by electric light, and showed the relative advantages of lighting by that means and by gas, and the necessity for the eyesight and health generally that the illumination should be a suitable one. This was the presidential address, and on the motion of Professor Ayrton, seconded by Professor Hughes, the General was accorded a hearty vote of thanks. Dr. Greenhill then read a paper on the "Health of Hastings" at the present time, compared with thirty-five years ago. He showed that the death-rate had decreased from 18.87 per 1,000 in 1854-54 (including the cholera year) to 14.43 at present time. In other respects there had also been an improvement, noticeable amongst them in the dwellings of the poor. The Sanitary Aid Association had done good work. Mr. G. B. Watters dealt with farm-yard sanitation, urging the importance of greater attention being paid to sanitation in the farm-yard, and showing the bad effects of dirtiness there. Mr. H. F. Lester, hon. sec. of the London Model Abbattoir Society, and Mr. E. A. Grattan, late British Consul-General for Belgium, advocated Abbattoirs, showing what a great improvement they were upon the present system of slaughtering animals. Mr. Hy. Colborne spoke on the meteorology of Hastings, showing how greatly favoured the town was in the amount of sunshine it enjoyed, and how sheltered it was, by reason of its situation, from the cold winds. The Borough Surveyor dealt with the water supply of Hastings. He described the sources from which the water was obtained, and the way in which the borough was supplied. He showed that the town was very fortunate in that respect. Mr. Keith Young showed the advantages of circular hospitals, and Dr. Bagshawe made some similar remarks. A very interesting debate took place in the afternoon of Thursday on "Cremation," Dr. Edward Haward advocating the incineration system. Mr. Seymour Haden, who could not be present, but whose address was read by Dr. Allen, advocated earth-to-earth burial as opposed to cremation, and argued that the body should be placed in a light coffin of wicker-work or similar substance, so that it would soon come under the destructive influences of the soil. Sir Spencer Wells showed how terrible was the state of the soil of churchyards. Cremation, he said, was also cheaper, and he also showed what he contended were the advantages of the system. Sir E. Chadwick, Rev. F. Lawrence, hon. sec. of the Burial Reformation Society, Mr. Hannen, hon. sec. of the Cremation Society, Dr. Richardson. Dr. Pietra Santa, and others, took part, the debate being of a most interesting character. In the evening Dr. Humphreys discoursed upon "Educational Overstrain," showing the evils which resulted from overwork, the address being extended in consequence of the unavoidable absence of Lord Brassey.

FRIDAY.

On Friday morning Dr. Bagshaw spoke on the "Preventive Side of Medicine," and then Miss A. Chreiman read a paper on "The Physical Culture of the Young," and was followed by Mr. Ed. Tidman, C.E., on the "Registration of Architects." Dr. Richardson read a paper on "Purification of the Air by Ozone," and an essay was presented by Lady Mount Temple and the Committee of the Ladies' Sanitary Association on "Women's Work in Sanitation." Another interesting subject debated was that of Vegetarianism, Mr. Knight, secretary of the Vegetarian Society, advocating that Association's principles, and Dr. Drysdale taking an opposite view. Considerable discussion followed. During the week the phonograph was on view at the hall, and large numbers of people were astounded by it. On Friday night a banquet was held at the Queen's Hotel, when a large and representative company was assembled. The principal toasts were: "The Houses of Parliament," given by Dr. Richardson, and responded to by Mr. Wilson Noble; "The town of Hastings," proposed by the President, and responded to by the Mayor; "The Leaders of Sanitation at Home and Abroad," submitted by Dr. Bagshawe, and acknowledged by Sir E. Chadwick, Dr. Pietra Santa, and Dr. Fisher (Canada); "The President," proposed by the Mayor, and suitably replied to; and the "Officers of the Congress," to which Dr. Richardson spoke, and to which Mr. Randell replied. On Saturday, in most lovely weather, a large company drove to Battle, Normanhurst, and Ashburnham, and in the evening, at the Royal Concert Hall, Dr. Richardson delivered an address on "The Health of the Body." A brilliant gathering was held at the Concert Hall, when the Mayor and Mayoress gave a conversazione, the audience including the members of the Conference, and many leading townsmen and townswomen, the proceedings proving of a very enjoyable character, and the gathering was a large one.

THE EXHIBITION.

The Exhibition was ready on Monday afternoon, April 29th, when, after lunching at the Brassey Institute, the Mayor, Corporation, and party, marched in procession to the specially-erected building in the Cricket Ground to perform the opening ceremony. At this time the hall was all in order, and looked most cheerful and attractive, with all the gay festooning of the flags and all the highly-coloured objects

ranged in striking positions throughout the annexe and the main body of the structure. After perambulating the various divisions of the show, the *cortege* at last returned to the platform, and, amidst applause, the speeches commenced. The mayor opened the exhibition with some well-chosen remarks, in the course of which he explained the origin of the exhibition, which had been first suggested in a chance conversation between himself and Dr. Richardson. The present undertaking he characterised as worthy of the high position held by Hastings and St. Leonards as a health resort, which he said was second to none in the kingdom, though other towns might have a position equal to it. Dr. Richardson followed and referred to the honour Sir Edwin Chadwick did them by his presence. He also spoke of the immense strides domestic sanitation had made during the past quarter of a century, and said that exhibitions such as this were amongst the best means of spreading the use of the many valuable health and sanitary appliances which of late years had been invented, and of educating the people in the most satisfactory management of their homes. He had seen many such exhibitions, and, according to what he could judge from a casual glance round the building, this was undoubtedly the best he had visited. He congratulated the Mayor and the borough generally on the success of the collection, and wished it every prosperity. Sir Edwin Chadwick then briefly spoke, and after a vote of thanks to the chairman for presiding, and the playing of the National Anthem by the band, under Mr. Haydon Millairs, the Mayor declared the exhibition open, and the formal proceedings closed with prayer offered by the Rev. T. L. Vaughan. The Mayor was seated on the rostrum which had been prepared for him in a prominent position in the annexe, and the Mayors of Lewes, Rye, Lichfield, Basingstoke, West Ham, and Hythe and the Corporation had their seats in the reserved portion below, where the Mayoress and Sir Edwin Chadwick were already seated. The exhibition was of a most miscellaneous character, as may be seen from the brief account I send of the principal stalls.

Entering the main building, and turning to the annexe, the first exhibit that attracted the eye was Messrs. Merryweather and Co.'s collection of fire appliances. Notable amongst these were the police ladder, which, by being detached, can be also used as an ambulance waggon, a fire engine and hose reel, and an ancient arrangement, used about the year 1585, for extinguishing conflagrations. We find here also a fire hose warranted to stand a pressure of 400lbs., and a Glenister-Merryweather Fire Engine, which should be particularly interesting to local people, from the fact of Chief Constable, who is also Captain of the Hastings Fire Brigade, being a part inventor. Next we came to some specimens—and admirable specimens too—of the skill of Mr. Campbell's firm of carriage makers. Chief amongst these exhibits were a circular-fronted brougham, fitted up with great luxuriousness, a Victoria, and a pretty four-wheeled dog cart. Near at hand was the establishment of P. Fosca, where sculpture was on view; and that of Mr. S. Deards, F.R.H.S., the inventor and patentee of the "Gold Medal" Victoria Dry Glazing and Champion Coil boiler, who has been awarded twenty-one gold, silver, and bronze medals and diplomas. Mr. Richards, of High-street, had for examination some medical appliances for delicate operations, and for the use of invalids. Messrs. Hamilton, of Brighton, who are the winners of several prize medals, had a number of couches which must be invaluable to invalids, inasmuch as special arrangements are made for support in unusual postures. Jeye's disinfectants, now so largely used, were just in their proper place—more appropriate than many of the other articles on view. Liddiard and Wordley showed many useful things, including patent screw and stationary ventilators, chimney pots and ventilating tubes. Jeye's sanitary pipes for domestic purposes were worthy of attention. Jaeger's woollen clothing was also shown in a stall specially set apart for its benefit. Messrs. Alderton, Keen, and Co.'s was another most attractive show, one of its special features being an assortment of pedestal lamps. Mr. C. W. Flint managed a stall containing Stott's Gas Governors. Mr. Rossitor, chemist, exhibited a number of his wares, and Messrs. Blomfield had some choice specimens of the photographic art, the plantinotype being the principal feature. E. M. Goggin's collection of bog oak ornaments commanded much admiration. On the right-hand side of the north annexe, Mr. Langley, of the Albert Hotel, had a refreshment department, and Fry's mineral waters. F. Stubbs, of London, showed some children's mail carts, which seem now to be all the rage, and Mr. J. D. Kenwade had some of Defries' patent safety lamps of all descriptions. Messrs. Alderton, Keen, and Co., had some excellent sanitary manufactures here, and Mr. J. G. Richards showed Turkish Baths for home use. Mr. Newing had some confectionery of a wholesome and desirable nature, and Mrs. Harman, of Verulam-place, shows a number of novelties for personal adornment. Other establishments hereabouts which were deserving of attention were those of Messrs. Burroughes, Welcome, and Co., Liddiard and Wordley, and the Pedeline Co. At the top of the right-hand avenue and crossing down the other side, Messrs. Wilson and Co., who supply the White Star Line with canvas, were located. Here also were various stalls, including those of the Messrs. Watkinson (boots and shoes), S. Smith, of London (quilaline, for cleaning purposes), J. C. Kenward (rocket air warmer, a local invention), D. Avis and Co. (heating and cooking stoves), Mrs. Lynn, J. C. Butler, Pink's, Fellows, Amon (block fuel), Randle (printing), Elliott (paving stone), and various others. In the central avenue (south) we had W. J. Hooper's jewellery establishment, and that of Messrs. Weston and Son, photographers, of St. Leonard's. Mr. Marriott, of Havelock-road, also showed some chemical appliances, and Amadoire and Co., of London, made a speciality of Roman rugs, coverlets, table covers, scarves, and shawls. A stall of perfumes was under the charge of Messrs. C. Hagen and Co., High Holborn. Messrs. Burroughs and Watts, the well-known billiard makers, were well to the fore in their branch of business, and their place attracts much attention. Amongst other things, they showed collapsible cues, switchback parlour skittles, and a table with Eureka cushions. They had also a department for other sporting materials. Fremlin Bros., brewers, exhibited many specimens of the ingredients used in the manufacture of their beers, and Jenner and Son, of St. Leonards, shew some new and improved hygienic boots and shoes. Notcutt and Son had a splendid display of Doulton ware, Tinworth's masterpieces, as exhibited at the Royal Academy, etc. Messrs. Slade and Messrs. Hermitage and Sons both showed a number of splendid musical instruments, and Ellis, Son, and Vidler had a selection of Nahan wines. The chief stalls in the South Avenue (south) were those of Hanmer and Co. (church furniture), the Eagle Range and Fountain Company, Bradford and Co. (machines), Greenhall and Co. (steam washers), Notcutt and Sons, Jennings, F. J. Parsons (printing machines at work, die stamping in operation, etc.), Crossley Bros. (Otto gas engine).

PROPOSAL FOR A PARLIAMENTARY INQUIRY ON HOSPITAL MANAGEMENT.

WE have received the subjoined draft of a proposed petition from the Charity Organisation Society. Gentlemen who approve of this petition, and are desirous of signing it, should send their names (on a separate slip of paper) to Mr. C. S. Loch, Charity Organisation Society, 15, Buckingham Street, Strand, W. C., from whom, also, forms of petition can be obtained.

To the Right Honourable the Lords Spiritual and Temporal of the United Kingdom of Great Britain and Ireland in Parliament assembled.

The Humble Petition of the London Society for Organising Charitable Relief and Repressing Mendicity and of others interested in hospital management.

Showeth as follows:

That the metropolitan hospitals, more particularly those to which are attached schools of medicine and surgery, are institutions in the well-being of which the community at large, rich and poor alike, have a direct and permanent interest;

That the sufficient support, good management, and thorough efficiency of these hospitals, whether as centres for the relief of poor persons suffering from disease or accident, or as schools for the advancement of medical education and practice and the furtherance of scientific research, are questions which may at the present time, for the reasons hereinafter stated, be with great public advantage submitted to the consideration of a Select Committee;

That there are in the metropolis eleven general hospitals with schools recognised by the licensing bodies for the examination of candidates for admission to the medical profession;

That the in-patients at these hospitals in the year 1887 numbered 44,364, and the out-patients 551,663;

That of these hospitals three are commonly known as the great endowed hospitals—namely, St. Bartholomew's, St. Thomas's, and Guy's Hospitals; that in 1887 the governors of Guy's Hospital, in order to enable them to carry on its work, had to raise a fund of £100,000 by means of voluntary contributions; while in the same year the governors of St. Thomas's Hospital expended £7,055 in excess of income.

That the other eight general hospitals published accounts, from which it is not possible to draw any certain statement as to the actual amount of their annual deficit; but that it would appear that, excluding legacies

and endowments on the one side, and extraordinary expenditure on the other, the annual expenditure may be estimated to exceed the income by about £51,700;

That, excluding hospitals or asylums for the incurable, cottage hospitals, and convalescent homes, there are eight general hospitals without schools and sixty-seven special hospitals in the metropolis with an income estimated at £294,500, and in- and out-patients estimated to number 32,500 and 505,150 respectively, that the data are not available for estimating with accuracy the annual deficit in the funds of these hospitals, but that it is on all hands admitted to be in many instances so considerable as to cause grave anxiety to those responsible for their proper maintenance;

That over and above the number of unoccupied beds required as a working margin in the administration of a hospital, there is reason to believe that at the present time a large number of beds are permanently unoccupied, owing to want of funds, though upon this point no certain estimates are forthcoming;

That besides the above hospitals there are thirty-nine voluntary or part-pay dispensaries, with an income estimated at £28,250, and out-patients estimated to number 264,500.

That in addition to all these institutions, and apart from the large provision made for the treatment of sickness in connection with friendly and benefit societies, there are thirty-one provident dispensaries, with an approximate income of £15,550 and 117,150 patients;

That, besides these voluntary hospitals and dispensaries, the poor-law authorities have now, in accordance with the Metropolitan Poor Act (30 Vict., c. 6), provided for the relief of the sick poor twenty-seven poor-law infirmaries, many of which, by reason of the suitability of their structure and the completeness of their arrangements for nursing and treatment, have assumed a place in the system of medical relief in London, which the hospitals alone filled before the year 1868; and that, consequently, there has of late years been a tendency to treat in these infirmaries not merely the cases of chronic illness or senile weakness which formerly found refuge in them, but maladies which require special and skilled medical care, such as could formerly be looked for only at the hospitals;

That it is estimated that since the year 1868 considerably more than £1,000,000 has been expended in the metropolis from the poor rates in the improvement, enlargement, and building of poor-law infirmaries and sick asylums, apart from the sum of £651,577 expended by the Metropolitan Asylums Board on nine hospitals and hospital ships for the treatment of infectious diseases; that from official returns it appears that, excluding the repayment of loans and the payment of interest, and deducting recoupments, the expenditure on the maintenance of twenty-three of the poor-law infirmaries and sick asylums, and their inmates, amounted, in the year 1887-8, to £336,205; and that in that year the number of days during which patients were severally maintained at these twenty-three institutions reached (exclusive of the cases of casual paupers) a total of 3,575,946;

That, further, forty-four poor-law dispensaries have been opened in different parts of London under the Act of 1868; that at these dispensaries, in 1887, 10,342 persons were treated who were on the permanent medical list, besides other cases in which 116,267 orders were granted, and that the number is apparently increasing from year to year;

That from the figures above quoted in respect of endowed, voluntary, and poor-law institutions, it would appear that ample provision has been made for the relief of the sick poor, and wide scope is afforded for the furtherance of medical education and scientific research;

That there are, however, in the present administration of medical relief in London some plain and very serious defects, of which many who are well qualified to judge are cognisant, and in regard to which complaint has frequently been made in the general and medical press;

That these defects touch very diverse, complex, and powerful interests, while as to their relative importance, and the remedies to be applied for their removal, there is the utmost difference of opinion;

That of these defects the following may more particularly be mentioned:

(1) The promiscuous congregation in out-patient departments of large crowds of persons who in most instances are suffering from slight ailments, for which skilled hospital treatment is quite unnecessary, is a constant hindrance to medical instruction, increases the discomfort and pain of those who are suffering from severe maladies, and occasions much vexatious and needless waiting.

(2) The indiscriminate admission to the benefits of hospitals and dispensaries tempts many who could pay for medical relief to become occasional recipients of charity, and by degrees habitual paupers.

(3) The provision of gratuitous medical relief to large numbers of persons, both as in- and out-patients, without inquiry or any sufficient regulation, is, as investigation shows, a serious obstacle to the promotion of provident institutions, at which medical treatment can be secured by small periodical payments.

(4) Hospitals and free dispensaries, as at present administered, usually offer no special advantages to those artisans and labourers who have combined to make provision against times of sickness, and there is no recognised relation between these hospitals and dispensaries and provident institutions.

(5) There is no clear and definite division of work between voluntary hospitals and dispensaries and poor-law infirmaries and dispensaries, but the former deal with cases which might more properly be left to the poor-law, and the latter with cases which from their medical interest or special requirements, or from the character and circumstances of the patient, might properly be treated in charitable institutions.

(6) By the multiplication of gratuitous and part-pay institutions, and the absence of regulation or organisation, those medical men whose practice lies among the poorer classes, are year by year more severely hampered in making a livehood.

(7) There is keen and continuous competition between hospitals, which spend year by year sums considerably larger than their average income would justify, and are thus driven to resort to all manner of contrivances to meet their liabilities.

(8) Year by year also new hospitals are (sometimes under very doubtful auspices) established for the treatment of special diseases, without any reference to the provision already available.

(9) The hospitals and dispensaries are often ill-grouped for local purposes, and though sometimes a hospital and one or more dispensaries are, from their position, conveniently placed for co-operation, there is no settled relation or agreement between them by which cases may be transferred from dispensary to hospital, and *vice versâ*.

(10) There is no uniform system of keeping and publishing accounts.

That on all these grounds, and inasmuch as there is now unfortunately no possibility of these defects being remedied by concerted action among the various institutions above referred to, it is a matter of urgent concern to the community at large, and not less to the hospitals, that all needful evidence should be collected and sifted, and the facts ascertained by an impartial body, such as a Select Committee, for only by this means will the information be forthcoming in accordance with which systematic reforms likely to be acceptable to all parties may be shaped, and the necessary ways and means agreed upon and provided.

Yours Petitioners therefore humbly pray your Right Honourable House that they will appoint a Select Committee, with special reference to the above statements, to make inquiry in regard to the financial and general management and the common organisation of medical institutions, endowed and voluntary, and in regard to the administration of poor-law institutions for the aid of the sick in the metropolis, and to make recommendations.

And your Petitioners will ever pray.

Signature. *Address.*

Surgical Aids and Appliances.

122.—A NEW NEEDLE-HOLDER FOR ALL KINDS OF NEEDLES.[1]

DR. W. W. VAN ARSDALE, Instructor in Surgery New York Polyclinic; Attending Surgeon Eastern Dispensary, has invented this needle. The jaws of the needle-holder work on the principle of Dr. G. R. Fowler's instrument, of Brooklyn. They are made smaller, however, so as to facilitate the application of buried sutures in small wounds, and, the joint being a French lock, straight needles can be retained in proper position by being placed behind the transverse portion of the jaws against the longitudinal surfaces of the shafts. While the

[1] Presented before the Section in Surgery of the New York Academy of Medicine, April, 1889. See *New York Medical Journal*, May 18th, 1889.

needle-holder, therefore, is especially intended for use with the Hagedorn needles, which are every day becoming more popular, it can be used equally well for straight needles, for needles partly or wholly curved on the flat, and for perfectly round needles.

In placing the flat Hagedorn needles in position, the same precaution should be taken as in the Hagedorn needle-holder proper—namely, that of placing the portion of the needle which bears the eye in contact with the right side of the shaft of the instrument. The point of the needle should emerge at the point of the beak of the instrument. This position allows of greater freedom of scope and of easier rotation of the handles. The present instrument holds even the smallest flat needles so firmly, however, that this point of position need not be insisted upon, as is the case with Professor Hagedorn's holder, which is frequently too weak in its action.

The shafts are sufficiently long to permit of placing sutures inside of cavities, though not too long to preclude delicate work in plastic operations. The instrument can be used for ophthalmic work, as small needles, curved on the flat, and held between the transverse portion of the jaws, can be closely approximated to the organ. The whole instrument is about seven inches in length in the present model. For use with the very largest flat needles made, it should be one or two sizes larger, the present one being intended for general use.

The handles are made of vulcanized rubber, conveniently fashioned to fit the hand, and can be made of any desired size to suit the operator. The posterior one is smaller than the anterior one, in order to facilitate rotation in suturing with curved needles; moreover, it is flattened on the surface, so that one can tell the position of the holder in the hand by the feel of it alone.

The catch consists of a tongue, provided with three angular ratchet-teeth, which fit into two retaining side bars in the opposite handle. When the first tooth is caught, the needle placed between the jaws is held moderately firm, and very firmly indeed when the second tooth operates; the third tooth, however, releases the catch by allowing the tongue to pass between the bars, and the instrument opens, releasing the needle. The action of the catch is in some sort automatic. By closing the handles of the instrument after placing the needle in position, the blades become locked, and remain so until the needle is passed, when simple further pressure upon the handles releases the needle, thus doing away with all difficult thumb movements necessary to release the needles in most other holders. In many holders the needle can only be released if the catch happens to be opposite the thumb of the operator; the present instrument can be readily opened in every position, even when held upside down.

The advantages of having a catch of some kind on a needle-holder are that an assistant can hand the instrument to the operator without danger of the needles falling out, and that when operating without assistance, the needle placed beforehand in the jaws will be retained in the proper position till the instrument is used. If, however, the operator prefers to hold the needle in the forceps uncaught while passing the sutures, he need only free the catch by pressure before passing the needle, and can then manipulate the instrument in the same manner as if it had no catch.

The instrument is a so-called antiseptic one. It can be instantly taken apart for cleaning. The blades readily come apart by means of the French lock. The two springs, which open the blades and work the ratchet-tongue, respectively, are made in one piece, and can be slid laterally out of the pivot-head which retains them. The tongue is moored in cannon-bearings provided with side-slots, from which it is easily disengaged after removal of the spring.

The hard-rubber handles are vulcanized on while the steel is still hot, and the whole is afterwards finished in one piece, presenting perfectly smooth surfaces. Even the name of the maker does not cause any unevenness of the surface, being made of metal and sunk into the handle so as to permit of a perfect finish, while remaining visible to the eye. The instrument is manufactured by the firm of George Tiemann & Co., of New York, and has proved very satisfactory.

123.—MEDICAL FIELD COMPANION (RICHARDSON'S).

VOLUNTEER surgeons going into camp with their regiments require a compact field companion, fitted up with medicines, etc. We have had a small companion fitted up for us by Messrs. John Richardson and Co., and we have found it answer admirably our requirements. The case is made regulation pattern, and when filled it can be easily carried by a bearer. The medicines can be selected by the surgeon, and if compressed tablets be selected this companion will hold enough medicine for even a campaign. Bandages, lint, vaseline, lanoline, iodoform, pills, tablets, can be stowed away compactly in one of these companions; and by a proper arrangement each article can be readily got at. A surgical haversack will also be found very useful fitted up according to regulation, with splints, bandages, tourniquets, dresser's case, etc.

124.—A SPLINT FOR USE AFTER TARSOTOMY.

MR. R. C. HOLT, L.R.C.S., Honorary Medical Officer, Victoria Hospital, Burnley, has devised this splint. The splint consists of a circular ring of iron, well padded; fixed to it are two parallel bars at right angles to the plane of the circle. To the distal ends of these bars is attached a footpiece which moves on hinges, and on the outer side of the footpiece are two hooks. After the operation for varus and the application of the dressings, the ring of the splint is passed up the leg, and the foot is securely bandaged to the footpiece at whatever angle it may be, for after the operation the foot still retains its deformity, partly on account of ligamentous attachments. Then the outer side of the ring and the outer side of the footpiece are connected by means of a rubber band ending in a chain to be hooked on to the footpiece, so as to have the tension required to bring the foot into shape. This may be altered according to circumstances.

The advantages of the splint are: 1. That the foot and leg are easily observed. 2. That the foot may be securely fixed without in any way interfering with the wound. 3. The tension is continuous and may be regulated. 4. The movements of the patient in no way interfere with its use.

In order to make the splint more useful, the hinges are made with movable pins, and at the heel end of the footpiece are the necessary portions of the hinge to fit on to the ends of the bars. Then it can be used for talipes equinus, there being hooks fitted on to the toe part of the footpiece.

The splint is made by Messrs. Down Brothers, 3, St. Thomas's Street, Borough.

125.—SUPPORT FOR THE LITHOTOMY POSITION.

Dr. W. C. WILE, of Danbury, Connecticut, has devised a simple apparatus for retaining the limbs of a patient in what is generally called the lithotomy position. It does away with the necessity for two assistants to hold the legs and thighs flexed, and conduces to greater steadiness of the perineum and buttocks. The apparatus was shown before the Section on Gynæcology at the thirty-ninth annual meeting of the American Medical Association.

The idea, in a general way, was derived, Dr. Wile states, from a pair somewhat similar in design, but not so perfect in mechanical construction, in the office of Dr. Bernays, of St. Louis. The most desirable apparatus must be one which will not impede the circulation of the blood of the limbs, or in any event do this as little as possible. The instrument is placed in position only after the patient is put under the influence of the anæsthetic, and on the top concave bar rests the belly of the gastrocnemius muscle, while in slots on each side of this is inserted a strap which passes around the sole of the foot, keeping the leg from slipping down, which would cause undue pressure on the popliteal artery under the knee-joint. Another point about this instrument is that the clamp holding the upright rod is so constructed that it is said to be impossible for it, under any strain which may be put upon it, to slip, the clamp grasping every portion of its periphery.

Medical Miscellanea.

THE subject of our next illustration will be Dr. Ward Cousins, Southsea.

* * * *

UNIVERSITY COLLEGE, LONDON.—Sir R. N. Fowler, M.P., the treasurer of University College, London, on Wednesday, May 15th, in the theatre of that College, distributed the medals and prizes in connection with the Faculty of Medicine. The Dean, Professor Marcus Beck, read the annual report, which stated that during the past year 340 students had attended the classes of the Medical Faculty and the practice of the hospital, ninety-nine of whom were new students. Out of a total of 207 who passed the various medical examinations of the University of London, forty-two, or 20 per cent., were from University College. Mr. F. W. Wesley won the entrance exhibition of £100; Mr. G. G. Spencer, of New Zealand, the exhibition of £60; and Mr. B. L. Abrahams that of £40. The Atchison scholarship of £60 per annum for two years has been awarded to Mr. T. L. Pennell; the Atkinson Morley scholarship of £45 for three years to Mr. W. H. Tate; and the Cluff memorial prize of £15 to Mr. A. Griffith. For the Bruce medals Mr. L. E. Hill and Mr. T. L. Pennell were the successful competitors. After distributing the medals and prizes, Sir R. N. Fowler addressed a few words of congratulation to the students.

Election of Examiners at the Royal College of Surgeons in Ireland.—At a meeting of the Council of the College held on Thursday, May 16th, the following gentlemen were elected Examiners for the College for the ensuing year:—*Anatomy and Surgery:* John Barton, William Stoker, William Thornley Stoker, Sir William Stokes. *Physiology, Histology, and Pathology:* Charles Coppinger, Richard A. Hayes. *Chemistry, Physics, and Materia Medica*: H. C. Tweedy. *Midwifery and Gynæcology:* Richard D. Purefoy. *Ophthalmology*: Arthur H. Benson. *Diploma in Midwifery*: Samuel R. Mason, Jer. O'Donovan, William Roe. *Diploma in Dentistry:* Daniel Corbet, jun., Robert Hazleton, George M. P. Murray, Henry G. Sherlock, William Stoker, Montgomery Albert Ward. *Diploma in Public Health:* Edmund W. Davy, D. Edgar Flinn, Edmund Lapper, J. Dallas Pratt. *General Education:* Michael A. Donnelly, Robert Morton, J. Dallas Pratt.

* * * *

Leprosy is said to be on the increase in Russia. During the last ten years, forty-nine patients were treated in the St. Petersburg hospitals, half of whom were natives of the city. The Baltic provinces suffer most from the disease.

* * * *

The next meeting of the Royal Commission on the Blind, the Deaf and the Dumb, etc., for the final consideration of their report, will be held about the middle of June, and it is anticipated that the report, evidence, and appendices will be ready for presentation very shortly after.

* * * *

Mr. James A. Campbell, M.P., occupied the chair at the dinner of the Glasgow University Club, London, at the Holborn Restaurant. In proposing the toast of "The Glasgow University Club, London," he said that the club tended to develop what had hitherto been neglected in the Scotch universities—the social aspect. For the information of those in the medical profession who are graduates of Glasgow University, and who may wish to join this club, we have pleasure in stating that the secretaries are Dr. G. A. Heron, F.R.C.P., 57, Harley-street, Cavendish-square, W., and Mr. J. R. McIlraith, barrister, 2, Essex-court, Temple, E.C.

* * * *

The annual dinner of the President and Council of the West London Medico-Chirurgical Society will take place on Friday, June 14th, at 7-30, at the Grosvenor Gallery, Dr. W. Travers, President of the Society, in the chair.

* * * *

Dr. Macarthur, Medical Officer of Grey Abbey Dispensary, has recently been presented with an address, along with an album and a purse of sovereigns. The presentation was made on the occasion of Dr. Macarthur's recovery from a severe illness.

* * * *

Mill collections of a penny per loom were recently made throughout the Blackburn district, towards a Fund opened as a memorial to the late Dr. Stephenson, medical officer for Blackburn, whose report, in 1887, gave fresh ground for the agitation against excessive steaming in weaving sheds. The Northern Counties Amalgamation, recognising the services Dr. Stephenson rendered to the Lancashire weavers, are giving the movement every support, and recommend collections all round. The fund already exceeds £1,000.

* * * *

Dr. F. G. Claxton Damian was last week entertained by a number of his personal friends at a farewell dinner, at the Royal Hotel, Grimsby. From the universal esteem in which Dr. Damian is held in the town and neighbourhood, the proceedings were of the most cordial character. The health of the guests was proposed by Drs. Stephenson and Allen, who each expressed, in appropriate terms, their high appreciation of the many valuable services rendered by Dr. Damian during his tenure of office as House-Surgeon to the Grimsby and District Hospital, and their great regret at his departure.

* * * *

Mr. Bolland Buck, wool-stapler, Bradford, lately deceased, has bequeathed the sum of £2,000 to the Rawson Convalescent Home, £1,000 of which is to be devoted to the building fund, and the remaining £1,000 to form the nucleus of an endowment fund. The testator has also bequeathed £1,000 to the Bradford Infirmary.

* * * *

"Were you wounded in the Crimea, Pat?"

"No, yer honor; the bullet hit me in the chist and kem out at me back."

"Why, Pat, that would have gone right through you heart."

"Och, faix, me heart was in me mouth."

Dr. Graily Hewitt has been elected a Fellow of the Royal Society of Edinburgh.

☞ We would direct the attention of our readers to the draft petition published at page 378, for a Parliamentary Enquiry on Hospital Management.

* * * *

Manchester Infirmary—A Suggestion.—At the monthly meeting of the Board of Management of the Manchester Royal Infirmary, a letter was read from Dr. Walter Whitehead, one of the honorary surgeons, enclosing a letter from Miss Lees, of Southport. A maid in the service of Miss Lees was recently treated in the Infirmary for a sore throat, with most successful results. Miss Lees wrote to Dr. Whitehead enclosing a cheque for twenty-five guineas. "I wish I could express to you," Miss Lees said, "how deeply indebted I feel to you for having saved the life of a valuable servant. She speaks most gratefully of the extreme kindness she received from yourself and all who attended to her during her stay at the Royal Infirmary." In his own letter Dr. Whitehead says:—"I have received the enclosed letter, containing a cheque for twenty-five guineas, from Miss Lees, of Southport. As it is evident that the object of Miss Lees's generosity is intended to express her appreciation of the general kindness her maid received during her treatment at the infirmary, I beg to forward her gift to the committee with a suggestion that the money may be allowed to form a nucleus of a fund for the benefit of superannuated infirmary nurses. In case the committee accede to this suggestion I shall be glad to supplement the amount by a personal donation of a further sum of twenty-five guineas." The Board agreed to adopt Dr. Whitehead's suggestion, and a vote of thanks for his gift.

* * * *

It is with feelings of sorrow, says the editor of the *St. Louis Medical and Surgical Journal*, that we are called upon to chronicle the death of Dr. Samuel Weissil Gross, Professor of the Principles of Surgery, and of Clinical Surgery at the Jefferson Medical College. He died of pneumonia in Philadelphia, April 16th, aged fifty-three. Dr. Gross was one of the leading surgeons of Philadelphia, and was an acknowledged authority on genito-urinary surgery, and on tumours of the female breast. He was a man who with generous impulses united the learning and skill of a master. Despite the overshadowing influence of his father, he had succeeded in thoroughly individualising himself, and his untimely demise will be learned with regret by all who have been so fortunate as to enter into personal relations with him.

* * * *

We have received the 151st Annual Report of the Queen Charlotte's Lying-in Hospital, and we are pleased to be able to make the following extract from it:—"In the nine years since 1879, when the sanitary arrangements of the Hospital were remodelled, 6,970 patients have been delivered in the Hospital, of whom fifty-four have died, giving a rate of mortality of 7.74 per 1,000. Since 1883, from which time the use of antiseptics has been carefully carried out, *the mortality has been* 4.6 *per* 1,000. From 1857 to 1879 the death-rate was 27 per 1,000. There were two maternal deaths among the out-patients, the rate of mortality being 1.73 per 1000." We can hardly credit *antiseptics alone* with the lowered mortality, other factors must be taken into account. In the out-patient department antiseptics could hardly secure such results.

* * * *

The Metropolitan and National Association, whose object is to provide the sick poor at their own homes with trained nurses, held its annual meeting at Grosvenor House on Monday, May 20th, under the presidency of Sir Rutherford Alcock, K.C.B. The report referred to the fact that its amalgamation with the Queen Victoria Jubilee Nurses Institution had during the year materially increased its usefulness; 870 cases had been nursed, and 19,200 visits paid during the year.

* * * *

A stormy meeting was held at the Suffolk General Hospital, Bury St. Edmunds, on May 21st, to consider a resolution which proposed to increase the number of honorary surgeons and assistant-surgeons. A similar proposal discussed at the last general meeting was strongly opposed by the medical staff, and rejected. Considering the reopening of the subject to be "vexatious in the extreme," Mr. J. Milner, Dr. Macnab, and Dr. Image tendered their resignation as medical officers of the hospital. After a prolonged discussion on May 31st, the meeting resolved to refer back the matter to the committee which had raised the subject, with instructions "to confer with the medical officers, to ascertain whether an increase of the staff is required." Meanwhile these gentlemen have been requested "to continue their services, so greatly appreciated by the Board, until the committee has reported."

Dr. Clifford Allbutt, F.R.S., Leeds, has been appointed by the Lord Chancellor a Commissioner in Lunacy.

* * * *

The Queen has forwarded a donation of fifty guineas to the Royal Maternity Hospital, Finsbury Square, of which she is a patron.

* * * *

We regret to announce the death of Dr. Robert McDonnell, F.R.S., one of the most distinguished surgeons in Dublin, which took place suddenly on May 6th.

* * * *

The refinement of medical education in America has gone so far that a chair has been created in the University of Vermont for instruction in examination for life assurance.

* * * *

Mr. Shirley Murphy, late Medical Officer of Health for St. Pancras, has been unanimously elected medical officer to the London County Council.

* * * *

The Metropolitan County Branch of the British Medical Association gave, on May 15th, a brilliant soiree at the South Kensington Museum. Nearly 2,000 guests were present.

* * * *

It is now stated that Lord Herschell will be the chairman of the new Vaccination Commission. It is not yet definitely settled who the members of the Commission are to be.

* * * *

We learn that Dr. Shoemaker (Philadelphia) has retired from the editorship of the *Medical Register*, which will be now know under the new title of the *Times and Register*.

* * * *

A public meeting was held, May 4th, in Davidson's Main School, when Dr. Thomas Russell was presented with his portrait and a purse of sovereigns. Mr. Robert Smith, Clemniston, stated that the gifts represented the kindly feelings with which Dr. Russell was regarded by a large circle of friends in the parish of Cramond. The portrait, which is an excellent likeness, is the work of Mr. R. E. Fraser.

* * * *

On May 25th, there was a conversazione of the Volunteer Medical Staff Corps at the hall of the Tallow Chandler's Company. Many novel inventions likely to be useful in the field were shown, of which perhaps the most noteworthy was an electric search lantern. When the wounded man is found by its aid, a surgeon can hook the lighted portion on his chest, and so perform any operation which may be immediately necessary. A stretcher which can also be used as a field hospital bed, and which packs into a wonderfully small space, seems a good invention. It is brought out by an American firm. The Medical Staff Corps has been in existence for four years, and now numbers 1,100 members. The Manchester Corps has held the Challenge Shield for the best work in "first-aid drill" continuously since the competitions began.

* * * *

We learn from the *New York Medical Journal*, of May 18th, a serious accident has happened with the suspension apparatus, resulting in the death of a medical practitioner while practising self-suspension alone. The accident is not unparalleled in this community, which still remembers the death of an estimable young lady in the same way, and orthopædic surgeons are cognizant of many instances in which only assistance coming in the very nick of time has warded off a like fatal disaster. There is danger that public knowledge of these matters, especially in the light of the sensational manner in which one of the newspapers has seen fit to lay the latest occurrence of the sort before its readers, will lead to a popular prejudice against the use of suspension. But it should be borne in mind that physicians accustomed to its employment have again and again given their warning against the use of the apparatus in the absence of adequate assistance. Only recently, indeed, Dr. Hammond said: "Though perfectly safe when due care is exercised, suspension should never be made use of except under the immediate supervision of a physician. . . . I am quite confident that we shall some day hear that a neck has been dislocated, and sudden death produced by the unskilful use of this method." The only safeguard seems to us to lie in the use of an apparatus that cannot be worked by one person alone.

A most successful soiree was given by the Medical Society of London on Monday, May 6th. The oration was given by Jonathan Hutchinson, Esq., F.R.S., and the band of the Royal Artillery was in attendance.

* * * *

M. Pasteur has accepted the invitation of the Council of the Royal Society to deliver the Croonian lecture on June 23rd. Should M. Pasteur's health not permit him to deliver the lecture, M. Roux will act as his deputy.

* * * *

A most successful Bazaar was held last week in aid of the Bootle Hospital, Liverpool, the gross takings being about £4,500. The expenses being only £200, it gave a net result to the hospital of over £4,250.

* * * *

The Princess of Wales, accompanied by the Prince, laid the foundation stone, on May 5th, of the new Hospital for Women, Euston Road. It will accommodate forty patients. The estimated cost is £20,000, of which £7,000 still remains to be subscribed.

* * * *

Dr. Lauder Brunton, F.R.S., has been announced to deliver the Croonian Lectures at the Royal College of Physicians, London, on June 6, 13, 20, 27, and July 4. The subject is "The connection between Chemical Constitution and Physiological Action."

* * * *

An International Congress of Otology and Laryngology will be held in Paris, from September 16th to 21st, at the Trocadero Palace. Those intending to read papers should forward the titles of their communications, before July 15th, to the secretary, Dr. Loewenberg, Rue Auber 15, Paris.

* * * *

The distribution of prizes of the Volunteer Medical Staff Corp will take place on June 1st at 5 p.m. Her Royal Highness the Princess Louise will distribute them. The dinner of the Volunteer Medical Staff Corps will take place at the Holborn Restaurant, the same day, at 7.15 p.m.

* * * *

Dr. Murdock Cameron, physician to the Maternity Hospital, Glasgow, performed the operation of Cæsarean section on May 9th with complete success in the case of a woman, who was only forty-eight inches high, and was much deformed. The mother and child are both doing well.

* * * *

The annual meeting of the American Medical Association will take place this year on June 25th, at Newport. The presidental address will be delivered by Dr. W. Dawson (Cincinnati). Dr. Pepper (Philadelphia) gives the address in medicine; Dr. Connor (Cincinnati) on surgery, and Dr. Welch (Baltimore) on State medicine.

* * * *

The fourth meeting of the French Surgical Congress will be held in Paris, from October 7th to 13th, under the presidency of Baron Larrey. The following subjects are proposed for discussion:—1. Results, immediate and remote, of operations performed for local tuberculosis. 2. Surgical treatment of peritonitis. 3. Treatment of aneurism.

* * * *

At a meeting of the National Health Society, held in the Parkes' Museum, the chairman, Mr. Ernest Hart, said it was very satisfactory to notice the large increase of work done by means of addresses delivered to the poorer classes in some of the poorer neighbourhoods in London, on "How to keep Homes Healthy and Clean, etc.," and also in educating classes by lectures on nursing, ambulance, and hygiene.

* * * *

FUNERAL OF DR. MACKERN.—The remains of Dr. Mackern, who died at his residence, The Limes, Long Eaton, on April 28th, were interred at Long Eaton Cemetery. There was a very large attendance. Dr. Mackern was highly respected by all classes. There were representatives from the Local Board, School Board, the "Fearfield" Masonic Lodge, the Liberal Association, and the Oddfellows' Lodge. There were no conveyances, the coffin being carried by railway enginemen. At the parish church, the Rev. C. P. Smith (vicar) and the Rev. Edmund Jackson (curate) conducted the service, and the procession was then re-formed, the coffin being carried to the cemetery, where a plain grave, covered with flowers, had been prepared at the request of the deceased. Wreaths were deposited on the grave in large numbers, one being from the Rangers' Football Club. Dr. Mackern was a native of Ireland. He was forty-nine years of age.

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the EDITOR, "*The Provincial Medical Journal*," *Horton House, Halifax.*

Matters of business should be addressed to the Publisher, at the Offices, 10, *Friar Lane, Leicester.*

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked.

Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16*th of the month.*

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

DIPHTHERIA IN SCHOOLS.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—What is the best thing to be done for all concerned when diphtheria makes its appearance in the confines of a large school where there are boarders and day scholars? Would it be more advantageous to have no boarders at the Government schools? How are European schools managed in this respect?—Yours truly,

PHILOS.

STATISTICAL INQUIRY.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—Can you oblige the writer by giving the statistics of the amount of money going out of England yearly for alcoholic productions into France, Germany, Switzerland, Italy, America, and other countries in which alcohol is less burdened with duty than it is in England, and also the round sum procured annually by the Scotch from the said advantage over the English in their enjoying a monopoly in the manufacturing of chloroform, ethers, flavouring essences, etc.? In our attempts at moral reform, is it really necessary that we should act recklessly in regard to our having to cope with foreigners in the markets of the world—nay, even in our own market? Is it possible that any man can be so foolish as to imagine that, because the agent in question has been or is liable to be abused, that, therefore, English manufacturing chemists and industries must be restricted in their productions, crippled and defeated by other nations, by our adopting and perpetuating such a needless and suicidal policy? It is plain enough that Johnny Bull is not only obstinate, but blind to some of his best interests.—Yours truly,

PHILALETHES.

ACUTE RHEUMATISM.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—I fail to see the reasonableness of Dr. Harkin's views regarding the nature and the effects of his treatment upon acute rheumatism. The disease, in my opinion, is an inflammatory affection of joints with or without cardiac mischief; certainly not dependent upon, or *originating in* cardiac inflammation, any more than is tonsillitis, or erythema nodosum, or even so simple a disorder as the common boil. When a cure results by applying a blister to the chest, it certainly acts as Dr. Harkin indicates; but there remains the fact that the blood, having its heat increased by the local stasis in the bloodvessels of the affected joints, has no other organ to depend upon for its circulation except the heart. Is that organ therefore, simply because it takes on an exalted action by reason of distal mischief, to be accused of originating the disease? I say, no.

Again, "*when the salicylates relieve temporarily or produce symptoms of poisoning, it is solely through their action as heart depressants.*" I demur to this also. I think it is solely through the obviation of stasis in the blood itself. Tension is thus relieved, and vaso-motor circulatory nerves are less irritated. When poisoning takes place from continuing their use too long, it is simply from the reduction of the hœmoglobin, as has been, I believe, experimentally shown.

I am, Sir, Yours truly,

May, 1889. C. R. ILLINGWORTH, M.D.

COMPULSORY VACCINATION.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

DEAR SIR,—It appears that there is some chance of a Royal Commission being appointed to inquire into the working of the Compulsory Vaccination Act. Under these circumstances it may be worth while to inquire into the logic of compulsion of this kind.

It is said that out of 750,000 children vaccinated annually some forty or fifty are really killed by erysipelas. In India, it is well known that when the hot weather is approaching, it is not safe to vaccinate infants, as the operation produces too great a disturbance in the system, and in the part vaccinated, ugly ulcers. In colder climates there may sometimes be other causes which produce fatal effects after vaccination. Everybody does not get small-pox, even when not vaccinated. The proportion given of deaths after this operation is small, but anti-vaccination parents say, "why should we risk killing any of our children by vaccination, in order to prevent their dying of small-pox?" As between forty and fifty out of 750,000 must be killed annually, there appears some reasonableness in the logic of such parents. For these to run any risk of killing a child by compulsion would appear maddening, especially as it is not a matter of certainty that, if not vaccinated, the child would perish. Confluent small-pox is loathsome enough, but all cases are not confluent.

At the same time that we have compulsory vaccination, we appear to have compulsory small-pox also. For it is stated that small-pox hospitals, such as that of Sheffield, and others, act as centres of active infection. The people living in the vicinity of small-pox hospitals might be entirely free from attacks of this disease, were it not for the concentrated infection from such institutions. Curiously enough, cases of small-pox in similar localities might perhaps be brought forward as evidence of the necessity of compulsory vaccination!

Anti-vaccinators say: "It is we who would suffer, if we got small-pox, then, why do you bother yourselves about us?" Vaccinators reply: "It is not only you that suffer, but we and ours would run the risk of getting small-pox from you." Anti-vaccinators then retort: "Very well, protect yourselves *ad libitum* by vaccination. This operation is either a protection, or it is not. If it is, you have an efficient means of protecting yourselves against infection, either from us or from other sources. We certainly do not object to *your* being vaccinated, even once a month if you like. What we object to is that our children should be subjected to the risk of being killed by this operation." The objections of anti-vaccinators appear to be rather unanswerable on logical grounds.

The vaccination of nurses who attend the sick in small-pox hospitals appears right enough, as these persons are wanted to do work, not to be laid up in bed with small-pox when they are employed in such hospitals. It is doubtful, however, whether the institution of extensive small-pox hospitals is not a mistake, when infected patients are gathered together, and concentrated infection manufactured from them for dissemination among people in the vicinity. Vaccination in the army and navy appears also right enough. The operation is performed on adults who are wanted for active service, and not to be laid up in hospitals.

But we are always trying to do illogical things from a spurious philanthropic desire to benefit others. The spuriousness consists in the fact that it is not seldom the love of exercising power, and of worrying others, which prompts this kind of philanthropy. There are many who are endeavouring to enact compulsory temperance, because some cannot touch liquor without abusing it, *ergo* it is considered necessary to enforce total abstention among those who can enjoy the wholesome use of it without abusing it! Others would like to enforce abstention from the use of meat, because they can do without it, and so forth. Such compulsions would appear to be as sensible as if we compelled every one to wear pink drawers, or a tail coat, or a cocked hat, because *we* liked them!

E. BONAVIA, M.D.

LATERAL CURVATURE OF THE SPINE.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—The reviewer of Mr. Bernard Roth's book "On the Treatment of Lateral Curvature," after agreeing with the writer in condemning instrumental treatment and advocating exercises, falls into the usual error of mixing up ordinary and medical gymnastics. He says, "one of the essentials of Roth's treatment is that the surgeon himself should carry out certain of the daily exercises, and this, we think, constitutes the difficult feature of the method. The majority of patients cannot possibly obtain such daily attendance, neither can the majority of practitioners find time to give them. It is the rich few only who can afford the luxury of a three months' residence in a surgical home, and in our opinion it is very rarely necessary. We have obtained excellent results by a judicious arrangements of periods of rest, regular gymnastic exercises, and *some kind of mechanical support, etc.*" I hold that herein lies the whole difference between Roth's system and that of most other surgeons. When consulted by the scoliotic patient, the surgeon probably gives certain directions as to constitutional treatment, dress, position, etc., and finishes by ordering a trapeze, a horizontal bar, or some other gymnastic apparatus, dismissing him (or her) with instructions to use them regularly, or possibly to join a gymnasium. This is all very well as a preventive measure for young girls or those who do not get a proper amount of physical exercise, and in whom *no deformity* exists, but entirely useless from a curative point of view, except possibly in the earliest "postural stage." We might as well attempt to teach music by directing the pupil to buy a piano or a violin. To carry out properly the "re-education of the patient's muscular sense, and the systematic training of spinal and other muscles," *it is essentially necessary that properly selected exercises should be systematically and regularly performed, if not by the surgeon himself, at all events as prescriptions, under his personal supervision, by assistants trained for the purpose.*

Then again the reviewer differs from Roth in supplementing (or nullifying) the effect of his *exercises* by "some kind of mechanical support," and so attempting to "shore up" the patients instead of inducing them to keep the body erect by their own gradually increasing muscular force. I could show several notable instances of the fallacy of such mixed treatment, the only results of which have been an increase of the deformity, together with painful contusions from the pressure of the *support* (?) Then as to expense. Although, when possible, it is far more satisfactory to keep the patient continually under the surgeon's eye during the greater part of the treatment, I quite admit that in a large proportion of cases this is impossible, from pecuniary and other reasons, but nevertheless the exercises can be very fairly carried out by a half hour *séance*, two or three times a week, at the surgeon's rooms; and even in hospital practice very good results may be obtained from a short prescription gone through, say once a fortnight, in either case the mother or some intelligent friend being present who will carefully watch the movements, see that all the instructions are fulfilled, and assist in the exercises night and morning, and from time to time as the muscular sense is re-educated, and the strength increased, others can be added, the expense of a worse than useless, and frequently costly instrument being dispensed with.

I hold that no form of treatment by which we can hope to benefit our patients should be considered derogatory to a surgeon; and in the commencement of my practice of medical gymnastics, I conducted the exercises personally, and frequently do so now; at the same time there is no difficulty in obtaining the services of competent assistants, who can be trained to fulfil the duties of "medical gymnasts" to carry out the prescriptions under the supervision of the surgeon. I would commend most strongly to all interested in the subject of lateral curvature a careful perusal of Mr. Bernard Roth's monograph.—Yours truly.

May 13th, 1889. EDWARD L. FREER.

Our Portrait Gallery.

J. WARD COUSINS, M.D. LOND., F.R.C.S.

THE face of Ward Cousins must be familiar to those who attend the annual meetings of the British Medical Association. Since 1873 he has been a member of the council, and has taken a very prominent part in all discussions, thoroughly throwing himself heart and soul into all duties connected with the council, feeling the British Medical Association was an object worthy of the highest labour. The spirit which animated the founders of the British Medical Association has been handed down and still survives, and among the present members of the council we have men who are influenced by the best traditions and the highest motives, so that the present management may be safely trusted, whilst the future would seem to be assured.

Dr. Ward Cousins is the second son of the Rev. T. Cousins, who for over sixty years was an Independent Minister, the greater part of whose life was spent in connection with King Street Church, Portsmouth. Dr. Cousins, after receiving sound elementary education, studied under the late Dr. E. J. Scott, who for many years was one of the leading operators in the South of England. He then matriculated at London University in 1853, and the same year entered St. Thomas's Hospital as a student. Taking his first qualification as a member of the College of the Surgeons of England in 1856 (Cheselden Medallist in the same year), he was appointed Resident Surgeon of the City of London Hospital for Diseases of the Chest. After proceeding to the Fellowship of the College, and the M.D. of London University, he settled in practice at Portsmouth. For twenty-six years he has been Surgeon to the Royal Portsmouth Hospital, practising surgery only. He has invented a number of surgical appliances, which gained a gold medal at the International Inventions' Exhibition. The following are a few of his contrivances: Antiseptic inhaler, self-adjusting tongue depressor, aural syringe for self-application, aural inflator, evacuator and injector, washable truss, capillary catheter and bladder aspirator, gag with throat guard, flexible eustachian catheter, pressure forceps, elastic cord tourniquet, pelvic tourniquet for amputation at the lip, bed clothes elevator with fracture swing and extension apparatus, antiseptic trocar (convertible into empyema knife), colotomy dilator, surgical needle and thread, convertible stethoscope (single and double), surgical bandage pin with handle, needle holder with rotatory action, fixation forceps, continuous evacuator in litholapaxy and other bladder operations, splint for fractures of the lower jaw, sound deadener, and an antiseptic artificial tympanic membrane.

He was awarded the prize of £20 by the British Medical Association for one of his inventions, but this money he did not himself receive, but offered it as a prize for the best essay on abortion. Dr. Robert Rentoul (Liverpool) was the winner of this prize, and we have a valuable acquisition to our literature in the essay which Dr. Robert Rentoul has just published. Dr. Cousins, besides other appointments, is Surgeon to the Portsmouth and South Hants Eye and Ear Hospital. For many years he has been engaged in the development of this institution, and a Surgical Home for Women; also in the reconstruction of the Royal Hospital at Portsmouth, which now has accommodation for 130 patients, and wards for special surgical cases. He has contributed many useful papers to current medical literature.

Dr. Ward Cousins is distinguished for his singular caligraphy, and his prescriptions have been a puzzle to many dispensers. Among the "illegible prescriptions" represented in "The Art of Dispensing," and published at the offices of the *Chemist and Druggist*, a *fac-simile* of his handwriting will be found.

We have had some experience of his writing, and we have to judge by the context, and by a few words which are legible, what his letters are about.

Original Communications.

THE CONNECTION BETWEEN MILK SUPPLY AND DISEASE.[1]

BY A. M. DAVIES, M.R.C.S.,

ASSISTANT PROFESSOR OF HYGIENE, ARMY MEDICAL SCHOOL, NETLEY.

AT the meeting of the International Medical Congress, held in London in the year 1881, Mr. Ernest Hart contributed a most valuable paper on "The Influence of Milk in Spreading Zymotic Disease,"[2] in which he tabulated a series of fifty epidemics of typhoid fever traceable to milk, fifteen epidemics of scarlatina, and seven of diphtheria, similarly traceable, as well as one outbreak of an anomalous character at Aberdeen, the cause and nature of which was not then fully made out, though the connection with the milk supply was evident. During the eight years that have elapsed since then, a considerable body of additional evidence has accumulated, and the scope of the enquiry has been widened, both by the inclusion of at least one other disease, in addition to the three just mentioned, and as well by the more extended views which have been recently expressed with reference to the mutual relationship existing between man and the domestic animals in regard to the communicability of disease.

The diseases, to the communicability of which through the medium of milk I wish to draw your attention, are: (1) Enteric fever, (2) scarlatina, (3) diphtheria, (4) tuberculosis. To these may be added some cases of *rare, but occasional* spread of other forms of disease, and some anomalous cases of acute poisoning.

I.—ENTERIC FEVER.

The fifty epidemics tabulated by Mr. Hart in 1881 included in round numbers 3,500 cases; of these epidemics, one occurred as far back as 1857, the others in the years 1870-1880. Though some of these are classical instances and familiar to most members of our profession, perhaps it will not be a waste of time if I refer to two or three of the most marked of them, in which the connection of the disease with the milk supply was demonstrated—almost with mathematical proof.

1. In July and August, 1870, an epidemic of typhoid broke out in Islington, which was reported on by Dr. Ballard. There were 175 cases and 30 deaths; of these 175 cases, every one occurred amongst the drinkers of the milk that was suspected; and out of 142 families that were supplied by the one particular milkman, 70 were invaded by the disease. These are two points that it is most necessary to state clearly and numerically—(i.) the number of cases that occur amongst the drinkers of the milk, which therefore may *possibly* owe their origin to that source; and (ii.) the number of families supplied with the milk, which therefore may *possibly* get infected from that source. In the present instance, the proportion was—for the first point 100 per cent., and for the second point 49 per cent. These cases mostly occurred within a limited area; the families attacked were in well-to-do circumstances; no insanitary condition was found to be common to the houses; the fever picked out customers of the dairy in particular streets and rows of houses; and finally, in many instances it was shown that it was especially the milk drinkers who were attacked. A tank at the business premises of the dairy, the water from which was used for "washing the cans" (which is often a euphemism for diluting the milk), was found to be in communication, by means of rat-burrows, with two old drains; but no *specific* pollution of this tank water could be traced.

2. Another classical instance is that of the Marylebone outbreak in July and August, 1873, investigated by Mr. Netten Radcliffe and Mr. Power. There were 244 cases and 26 deaths; of these 244, 218 were drinkers of the suspected milk, *i.e.*, 89 per cent.; while of 760 families supplied from the dairy, 118, or 15 per cent., were invaded by the disease. All the cases occurred in the nine weeks ending 30th August, and within a circumscribed area, mostly amongst well-to-do people, in houses without any community of sewerage or water-supply. The disease picked out the streets to which the milk was distributed; and, moreover, an isolated group of twelve cases occurred in another part of London, where there was a branch of the suspected dairy, and where eleven out of the twelve cases purchased the milk. The implicated farm only supplied about one-sixth of the ordinary milk distributed by the dairy, and this will account for the partial incidence of the fever upon the customers, only 15 per cent. of the households supplied being affected. At this farm water was used for dairy purposes that was obtained from a well liable to pollution from its position. The farmer on June 8th died suddenly of ambulant typhoid. The stools had been buried in an ash heap, whence they might have gained access to the well; and there were heavy rains on June 29th, which would render this more likely. Therefore, a specific source of infection was, at the very least, possible.

3. A much greater incidence of the disease upon the customers of the suspected milk supply was found in the outbreak at Eagley and Bolton (Lancashire) in January and February, 1876, investigated by Mr. Power and Mr. Robinson. Here there were 195 cases and 13 deaths; and of 59 families supplied with this milk, 55 were attacked, *i.e.*, 95 per cent.; while in eight families otherwise supplied that were attacked, in six out of the eight the members had been partakers of this milk at their neighbours' houses. Another series of 144 cases, with eight deaths, occurred at Bolton, two miles distant; and out of 50 families supplied from the same dairy, 47, *i.e.*, 94 per cent., were invaded. The neighbourhood had been free from fever, or other illness, for some months, and there was no community of drainage or water-supply to the district affected. The water-supply of the dairy farm-house was derived from a brook exposed to excremental pollution, and large quantities of fæcal mattter were actually found in the brook, though no specific contagion could be traced.

4. A widespread outbreak occurred in Glasgow in April, 1880, reported by Dr. J. B. Russell, in which there were 508 cases and 69 deaths—373 cases, or 73 per cent., being amongst drinkers of the suspected milk. The dairy was supplied with milk from thirty farms, all of which appeared to be in good sanitary condition, except one; here was a well exposed to possible pollution from a dung-heap, and on this dung-heap had been thrown excreta from enteric cases. A dairyman at this farm sickened with enteric fever in March, and subsequently two children of the farmer. Another girl, who passed a night in the house in nursing one of these children, partook of the milk, and sickened fourteen days after. On the day after the two children sickened, the first lot of milk was sent into Glasgow, and *exactly fourteen days afterwards*, the first case

[1] Read before the Southampton Medical Society.

[2] *Transactions*, International Medical Congress, 1881, iv., 491.

in the area of the milk supply fell ill. "The entire body of trade was tainted. It was associated with fever in the dairyman's own household, in persons served direct from his own cart; it poisoned the families of the dealers through whose shops it passed to the public; and it poisoned the customers who dealt at those shops." The milk supply was stopped, and the epidemic died out.

5. An epidemic of 44 cases, with 8 deaths, occurred at Worthing in October and November, 1880, reported by Dr. Kelly, in which every one (*i.e.*, 100 per cent.) of these 44 cases occurred amongst the customers of a particular dairy, in different parts of the town. A shallow well was used for dairy purposes, into which was traced soakage from a defective drain, leading from a house in which a fever case had occurred.

EPIDEMICS OF MILK-TYPHOID.

No.	Date.	Place.	Reporter and Reference	No. of Cases	No. of Deaths	No. of cases among drinkers of suspected milk.	Per cent.	Circumstances of Outbreaks.
1	1880 Sept., Oct.	Bridlington	Dr. Parsons, *San. Rec.*, Sep., 1881	48	..	48	..	Well at dairy liable to pollution. Case of typhoid at dairy.
2	1882	Leicester Infirmary	Dr. Elgar Buck, *San. Rec.*, June, 1882	12	..	12	..	All cases drinkers of raw milk. Well at farm liable to pollution. Milk purveyor died from typhoid.
3	1882 May, June	Glasgow	Dr. Russell, *B.M.J.*, July 8, 1882	59	6	50	85	Nearly all the cases occurred in one week.
4	1882	Clapham	*B.M.J.*, Aug. 5, 1882	20	..	19	95	All cases occurred within twenty-four hours.
5	1882	Halifax—Stone Chair	Dr. Britton, *B.M.J.*, Oct. 14, 1882	11	1	11	100	Untrapped drain in room where milk was stored; polluted water. Two cases of probable typhoid at farm.
6	1883	St. Pancras	Mr. Shirley Murphy, *Prac.*, 1883, xxxi., 386	..	..	..	..	Outbreak traced to a particular milk-supply from St. Albans.
7	1883 Oct., Dec.	New York—Port Jervis	Dr. F. C. Curtis, *Lancet*, Feb. 7, 1885	148	..	128	87	Out of about 500 consumers of suspected milk, 128 cases occurred. Sudden outbreak; sudden cessation. Typhoid cases at dairy farm.
8	1883 Oct.	Dundee	*B.M.J.*, 1883, ii., 839	..	..	36	..	Typhoid at dairy.
9	1883	Stricken, near Aberdeen	*B.M.J.*, 1883, ii., 1146	..	..	..	..	Typhoid at farm.
10	1884 May, June	St. Albans	Mr. Shirley Murphy, L.G.B. Supp. for 1884, also Dr. C. E. Saunders, *B.M.J.*, 1884, i., 1162 and ii., 1086	131	23	..	..	Six different retailers, all of whom drew a portion of their supply from a particular farm where there was typhoid Of 396 houses supplied with suspected milk, 86, or 21.7 per cent., were invaded. 2,127 houses within city boundary otherwise supplied, of which three only, or .14 per cent., were invaded. Total number of houses invaded, 90. Some of the milk was sent to London, and fever cases occurred in connection.
11	1884 Aug., Sept.	Glasgow Hospitals	Dr. J. B. Russell, *B.M.J.*, 1884, ii., 626, 724	143	32	..	..	At one of the dairy farms whence milk was supplied cattle suffered from a disease possibly due to bad drinking water. Dairy maid had typhoid.
12	1884 Oct.	Derby	*B.M.J.*, 1884, ii., 786	..	..	..	..	Well liable to pollution, and case of typhoid at dairy farm.
13	1884	Tweedmouth	*San. Rec.*, Nov., 1884	23	..	..	..	Typhoid at milkman's house.
14	1886	Lancing College	Dr. Kelly, *Prac.*, xxxvii., 223	14	2	14	100	Outbreak traced to partaking of strawberries and cream. Well at dairy whence cream was supplied liable to pollution. Many other fever cases in Shoreham connected with same dairy.
15	1886-7	Carlisle	Dr. W. Brown, *Practitioner*, xl., 383	25	..	24	96	Typhoid at dairy; also a febrile disorder among the cows previously.
16	1886	Swanage	Mr. W. Harvey, L.G.B. Supp. for 1886	..	..	..	..	
17	1888	Evesham	Mr. Fosbroke, *Pub. Hea.*, Feb., 1889	6	1	5	83	Typhoid at dairy. Polluted water. Milk adulterated.
18	1888 Aug., Nov.	Spennymoor	Dr. Spear, *Pub. Hea.*, June, 1889	..	..	..	..	Nineteen families attacked; eleven supplied from particular farm. Families supplied from this source, 144; supplied otherwise, 500. Relative incidence of fever 7.5 and 1.6 per cent. Typhoid at farm, and polluted water. Dr. Spear doubts causal connection of milk supply.
19	1889 Feb.	Stirling	Dr. McFadyen, *B.M.J.*, June 1, 1889	40	4	?40	?100	Water polluted; typhoid at farm; air of milk-house liable to pollution. All cases which occurred were supplied with milk which had been kept overnight in the milk-house; families supplied direct from the byre escaped.

I have selected these five instances, out of the fifty collected by Mr. Ernest Hart, as being very typical, and each illustrating especially one aspect of the subject. In the Islington epidemic of 1873, out of 175 cases, every one (*i.e.*, 100 per cent.) occurred amongst the drinkers of the suspected milk; but there was no evidence of specific typhoid pollution. In the Marylebone epidemic of 1873, there was strong evidence of specific pollution; and out of 244 cases, 89 per cent. were suspected milk drinkers. In the Eagley and Bolton epidemic of 1876, though no specific infection could be traced, 95 per cent. of the families supplied from the suspected source were invaded by the disease. In the widespread outbreak at Glasgow in 1880, specific pollution seemed proved, and the incubation period of fourteen days seemed established. While, lastly, in the 1880 epidemic at Worthing, every one of the 44 cases (*i.e.*, 100 per cent.) occurred amongst the suspected milk drinkers, and specific pollution appeared most probable.

I have collected notes of nineteen epidemics subsequently to those tabulated by Mr. Hart, some details of which appear in the accompanying table. Three of these instances, however, especially present points worthy of notice.

1. An outbreak[1] occurred in 1884 in the Glasgow Hospitals, attacking successively the Western Infirmary, the Royal, and the Belvidere. This was traced conclusively by Dr. Russell to the milk supplied from one particular farm. At this farm a dairy-maid was attacked by enteric fever at the same time as the outbreak in Glasgow; but before this the cows had been suffering from a febrile disease which a local veterinary surgeon attributed to the badness of the drinking water. This water was found to be grossly contaminated with sewage products, and enteric fever was endemic in the adjacent villages. Here there is a possibility of the typhoid having occurred at the dairy farm in an ordinary way, having been conveyed there from an adjacent focus of infection; and there is also a possibility of a connection between the first case at the dairy and disease among the cows.

[1] *British Medical Journal*, 1884, ii., 626, 724.

2. A small outbreak[1] occurred at Carlisle in 1886-7, traced unmistakably to a dairy where typhoid cases had existed. But there was nothing to show how these cases had originated, water supply and sanitation being quite good, except that the cows had suffered from a febrile disorder previously.

3. An epidemic[2] broke out at Lancing College in 1886, where the sanitary surroundings seemed perfect, and where there was a private dairy farm attached to the college, in perfect order. After very careful investigation it was found that some cream—partaken of as strawberries and cream—was the cause of the outbreak. No specific pollution could be traced, though there was a well at the particular diary (in the neighbouring town where the cream was procured) which was exposed to fæcal contamination.

Of Mr. Hart's fifty epidemics, thirty-nine appear to be distinctly traceable to a specific pollution with typhoid contagium; in six there is no record; and in five it is stated that there is no evidence to point to this source of infection.

Of the nineteen outbreaks I have brought together, twelve appear to be traceable to specific pollution; in three there is no record; in four there is possible or probable contamination; while in two of the cases, although specific infection was possible, it appeared as if some cow disease might have been the cause of the infective property of the milk. One important fact was repeatedly noticed in investigating these epidemics—that in a very large number of cases the incidence of the disease fell mostly upon those who drank milk in large quantities, children for instance, and particularly upon those who drank it "from the cow," as it is said, or "straight from the dairy,"—*i.e.*, unboiled.

Now, assuming that enteric fever can be spread by means of milk, which I think this body of evidence justifies us in doing (although in France and Germany such is not the opinion, at any rate, universally), in what manner, or in what different kinds of manner is the infection brought about? It may occur conceivably in one or more of four different kinds of ways:—

1. As water is the most common vehicle for the spread of the typhoid contagium, this latter may gain access to milk either (*a*) through the deliberate addition of water to the milk as an adulterant; or (*b*) through the use of water for washing milk cans or dairy utensils.

2. Supposing that the specific contagium, of whatever nature it be, is floating about in the air, as in particles of dried excrement in dust, it may sink down on to exposed surfaces of milk, and impart to the milk an infective property.

3. The contagium may be communicated to the milk through anyone combining the functions of milk seller, dairyman or dairymaid, and sick nurse to a typhoid patient, by means of soiled hands or the like.

4. Lastly, it is *possible* that cows may suffer from some such disease, communicable to man through the medium of the milk.

To one of these four categories, I think, must be assigned every instance of spread of the disease through milk; probably the great majority of cases are due to the first manner, while until dairies and milkshops are effectively supervised as to their sanitary conditions, and the health of their inmates, the second and third methods of infection are sure to be found to occur. The last way, from a disease of the cow itself, is as yet without anything approaching proof, but the two outbreaks mentioned—at Glasgow and Carlisle—have served to direct attention to the matter, which is, *a priori*, not inconceivable.

II.—SCARLATINA.

Up to 1881 Mr. Hart tabulated only fifteen outbreaks of scarlatina traceable to milk infection.

1. Of these, the first, in 1867, was described by Dr. M. W. Taylor, of Penrith (who had also described the first epidemic of milk typhoid ten years earlier). In this instance there were 111 cases, and all of them were drinkers of the suspected milk, the milk retailer's child suffering from scarlet fever.

2. Another noted instance occurred in South Kensington, and was investigated by Dr. George Buchanan, in 1875. On June 9th a dinner party was given in that neighbourhood, of sixteen persons; about 150 guests assembled in the drawing room after dinner, and fourteen servants were engaged in waiting. Between June 11th and 14th, out of these 180 persons, eighteen fell ill either with scarlatina or sore throat, as well as one other case, that of a lady who lunched at the house next day. There was but little scarlatina in the locality, and except for the meeting at this particular house, no common centre of infection, or other common local circumstance, to account in any degree for the disease attacking these particular persons. The only circumstance that afforded any explanation of the attacks was the cream supply, which came exceptionally from a London dairy. All who were taken ill had partaken of cream in one form or another, and all the ladies who took cream in coffee after dinner—to the number of seven—became ill; also all the ladies—four—who partook of cream dishes at lunch the next day were attacked. It is gratifying to know that no deaths occurred.

3. In June, 1879, several remarkably sudden and rapidly fatal cases occurred in a particular district at Newcastle-on-Tyne. Out of twenty-three cases ten died. The milk supplied was derived from one particular source in every case, with one exception. But no scarlatinal infection could be traced, even after the most careful enquiry.

4. At Fallowfield near Manchester, in August, 1879, there were thirty-five cases within a month, of which twenty-four were attacked within a space of thirty-six hours. They were all drinkers of a particular milk, and one of the milkers was lodging in a house where his grandchild was desquamating after scarlet fever. From the character of the surroundings, carriage of infection was most probable.

5. At Ilkley in Yorkshire, in November, 1880, a small outbreak of ten cases occurred, all drinking milk furnished by one purveyor. There was no disease at any of the farms or dairies, but the custom at this place was for the milkman to take his milk *into* his customers' houses in *bulk*, and this particular milkman had provided a family in which the children had been attacked with scarlet fever a month previously, and were therefore now in the desquamating stage—hence the probable absorption of infective material by the milk.

6. The most extensive epidemic reported was one that occurred at Halifax in 1881, with 510 cases and 86 deaths. Out of 135 families supplied by the dairyman, 53, or 39 per cent. were invaded. The circumstances pointed conclusively to the infection of the milk from scarlatina in the family of the farmer's man, who milked the cows and distributed the milk.

These cases are all noteworthy as showing, either (1) as in the first and sixth instances, at Penrith and Halifax, the large incidence of the disease on the suspected milk drinkers: of 111 cases of scarlatina, *all* drank the milk; of 135 families supplied, 39 per cent. were affected; or (2) the suddenness and fatality that may mark an outbreak of milk-scarlatina, 10 deaths out of 23 cases; or (3) the manner in which infection may be carried, as by the hands of the milker, or even, during the distribution of the milk, by visiting an infected house; (4) the epidemic due to use of cream is also remarkable.

I have collected notes of eighteen epidemics since those recorded by Mr. Hart, in three of which I can get no record whether or not the specific contagium of scarlatina was likely to gain access to the milk; in seven the disease existed at the dairy or farm whence the milk came; in three instances no specific connection with scarlet fever could be made out after most careful enquiry, but there seemed to be a causal connection between a disease of the teats or udders of the cow and the incidence of the scarlatina upon milk consumers; in one other instance there was a doubtful possibility of such a connection; in one instance a possibly scarlatinal sore throat at the dairy; in two instances nothing could be made out, except that in each case a cow had calved recently; and in one instance a particular brand of condensed milk was considered to be the cause of the outbreak.

This question of the possibility of the communication of the disease from cow to man—*i.e.*, of the existence of bovine scarlatina, is a most important one, and the literature of the subject has become very extensive during the last two or three years. It is difficult to summarise the observations and conclusions of the various investigators, and especially so since so much warmth has been thrown into the discussion. I will try to indicate briefly the principal points in the controversy so far as it has proceeded at present.

1. *The Russell Square Outbreak of* 1882.[1]—In January, 1882, occurred an outbreak of scarlatina in the Russell-square district, which was found to be connected with the milk supply from a particular dairy. One of the milk carriers and his children had sore throat and scarlet fever; but it was then found that some persons were supplied with this milk from the cart *en route* between Charing-cross Railway Station and the dairy, and, therefore, before the milk came near this affected milk carrier, and that amongst these persons also scarlatina broke out. Further, thirty-nine cases of the disease occurred at Camberwell, quite removed from the dairy and its area of supply, of whom thirty-two drank the milk derived from the same farm at Farnham; also the railway officials at Charing-cross had thirteen cases of scarlet fever and sore throat, at about the same time, amongst purchasers of this milk. Mr. Power then investigated the circumstances of the dairy farm. There was no scarlet fever—no insanitary condition. A cow had calved at the beginning of January, but had not been in any way ill. On 11th February Mr. Power found she had lost portions of her coat.

2. *Marylebone Outbreak*, 1885. *The Hendon Cow Disease.*[2] In November and December, 1885, an epidemic broke out

EPIDEMICS OF MILK-SCARLATINA.

13	1888 Jan., Feb.	Jesmond, Newcastle	Dr. H. Armstrong, *Pub. Hea.*, May, Oct., '88	19	..	17	..	Scarlet fever at dairy farm three or four months previously. One or two cows slightly denuded of hair.
14	1888 Mar.	Garnethill, Glasgow	Dr. Russell. *B.M.J.*, Oct. 27, 1888	95	..	95	100	Many other cases of scarlatina and sore throat among other families supplied by same dairy, outside this local epidemic. Three deaths in all.
15	1888 June.	Pollokshiels, Glasgow	Dr. Carmichael, *B.M.J.*, July 7, 1888	70	..	..	..	Scarlet fever at dairy farm.
16	1888 Aug.	Newcastle	Dr. H. Armstrong, *Pub. Hea.*, Sept., 1888	74	..	61	67	Throat illness in family of one of the dairy helpers. Five out of 24 cases of diphtheria among drinkers of same milk.
17	1888 Oct.	Garnethill (Pk.), Glasgow	Dr. Russell, *Pub. Hea.*, Feb., 1889	56	..	..	..	Scarlet fever and sore throat at dairy. In one district, out of 600 households, of 92 supplied by this dairy, fourteen were infected. Of 502 otherwise supplied, only two were infected.
18	1888 Dec.	Govan	*San. Rec.*, Feb., 1889	37	..	35	94	Of 74 families supplied with suspected milk, 23 attacked with 35 cases. Only two cases amongst 603 families otherwise supplied. Origin unknown.

[1] L.G.B. Report. Supp. for 1882. App. A 9.
[2] L.G.B. Report. Supp. for 1885. App. A 8.

in Marylebone, also in St. Pancras and at Hampstead and Hendon, which was investigated by Mr. Power, and the conclusion was come to by him that this outbreak was due to infection from the milk from a particular dairy at Hendon. He could discover no scarlet fever either at, or in the neighbourhood of the dairy. He examined the cows at the dairy, and found some of them to be suffering from an ulcerative disease of the teats and udders. Various circumstances connected with the time of arrival at the dairy farm of certain cows, the distribution of their milk, and the outbreak and incidence of the disease, led him to the belief that these cows, through some condition or other, were the cause of the epidemic.

Dr. Klein then continued the investigation for the Local Government Board, and made bacteriological experiments, both with these cows and with blood from scarlet fever patients. He was able to isolate a streptococcus from the ulcers on the teats of the cow, and in five out of eleven human patients he found what he believed to be the same organism in the blood. This organism was not present during the first four days, but appeared on the fourth and subsequent days. He performed experiments on animals with the organisms derived from these two sources, and obtained what he believed to be identical results and symptoms. The *post-mortem* appearances in the cow suffering from the Hendon disease, and in the animals inoculated with the streptococcus, were, he considered, similar to those found after scarlet fever. In short, the micro-organisms, the symptoms, and the *post-mortem* appearances, seemed to correspond.

Subsequently Dr. Klein found[1] that inoculation of this streptococcus produced ulcers on the teats in cows that had recently calved. He also found a similar micrococcus in a particular brand of condensed milk, which had been suspected of causing scarlet fever; also in the blood of a monkey that had died of the disease. Dr. Klein, therefore, named this organism *Micrococcus scarlatinæ*, considering that the disease was produced by its agency both in man and in cows, and that milk from cows so affected would produce the disease in man. This is the end of the first stage in the enquiry.

The Edinburgh Researches.—Dr. Jamieson and Dr. Edington made investigations[2] shortly after the publication of Dr. Klein's report. Various organisms were found in the blood of scarlet fever patients, their nature varying with the time at which they were taken. Dr. Edington considered those found during the first three days, which were bacilli, to be the cause. These disappeared from the blood after the third day, and reappeared again in the scales at the desquamating stage. When these disappeared from the blood others were found, amongst them one called by Edington *Streptococcus rubiginosus*, similar to Klein's micrococcus. Edington experimented on animals with this, and obtained appearances like scarlet fever.

The Medico-Chirurgical Society of Edinburgh made a preliminary report[3] on this research, to the effect that they consider Edington's and Klein's streptococci to be very similar, if not identical, but that there is no definite conclusion to be come to about the bacilli.

Dr. Thin's Criticism.—At the Dublin meeting of the British Medical Association in August, 1887, Dr. Thin criticised[4] what had been done so far. He found that at the same time that the Hendon cows were affected, other herds were also attacked by the same disease, the infection having originally started in a herd in Derbyshire; but no outbreak of scarlet fever had occurred among the consumers of the milk supplied from these other dairy farms. Further, the milkers at some of these dairy farms had no scarlatinal symptoms, *but* they had pimples and sores on their hands. Dr. Thin considered this Hendon disease to be *cow-pox*, and that the scarlet fever outbreak was possibly to be traced to a laundry in the neighbourhood, where some of the milkers resided.

Professor Crookshank.—Then the Agricultural Department of the Privy Council deputed Professor Crookshank to investigate the matter, and in December, 1887, he published his observations at a meeting of the Pathological Society.[1] After some delay and difficulty he succeeded in meeting with cases of cow disease in Wiltshire, which he believed to be identical with the Hendon disease, and he isolated a streptococcus. No scarlet fever occurred amongst the consumers of milk from this herd of cows, though it was extensively distributed. Dr. Crookshank believed the disease to be true Jennerian cow-pox. The milkers were affected with cow-pox eruption.

Dr. Klein, in his reply, denied the identity of this disease with the Hendon disease on the ground that the eruption was not the same, that the streptococcus did not grow in the same way, and that the milkers were not affected at Hendon with any eruption, as they were in Dr. Thin's and Dr. Crookshank's cases.

At the January (1888) meeting of the Pathological Society, Crookshank brought forward the results of further investigations.[2] He summarised his conclusions thus:—

1. The nature of the contagium of scarlet fever is unknown.

2. The micro-organism regarded by Dr. Klein as the contagium is the *Streptococcus pyogenes*.

3. This is found, sometimes in company with *Staphylococcus pyogenes aureus*, as a secondary result in scarlet fever, and in many other diseases.

4. Its exact relation to scarlet fever, and its identity with the streptococcus from pus and puerperal fever, was definitely established in 1885 by Fränkel and Freudenberg.

5. Both Wiltshire and Hendon cow diseases were called cow-pox by the people on the farms.

6. They correspond in clinical history.

7. The ulcers on teats correspond to the naked eye and in microscopic appearances, and the latter vividly recall the appearances of cow-pox.

8. Calves inoculated from the ulcers are similarly affected.

9. *Post-mortem* examination of such calves, and of calves inoculated from scarlet fever cases, show similar appearances.

10. These *post-mortem* appearances in calves are the result of septicæmia.

11. There are no specific visceral changes in cow-pox apart from complications or coincident affections.

Dr. Klein replied,[3] maintaining that the organism he had described as *M. scarlatinæ* was not the same as *S. pyogenes*, and that the Hendon cow disease was not the same as the Wilts. and the Edinburgh disease, one clinical difference being that at Hendon the ulcers only commenced on the fourth, while in Wilts. they were at their height on

the fifth day. In the Edinburgh cows the ulcerations occurred still later; therefore there were probably three diseases, not one.

A discussion followed, in which it was admitted that the subject was still in great confusion.

The subject was considered at the August meeting of the British Medical Association in Glasgow, 1888, but nothing of importance was elicited.

Professor Brown's Report to the Privy Council.—Towards the end of 1888 Professor Brown, of the Royal Veterinary College, presented a report[1] embodying Crookshank's researches and other investigations by veterinary surgeons and inspectors. An important point in this report is the statement by Professor Axe that there were cases of scarlet fever existing in Hendon, and that there was thus the possibility of human infection being conveyed to the dairy at the time of the Marylebone outbreak. Mr. Axe also states that an outbreak of udder disease amongst cows at Hendon occurred in 1887, precisely similar to the former one, but not accompanied by any scarlet fever amongst the consumers of the milk. In addition, he gives the history of four other batches of cows, all derived from the original Derbyshire herd, each suffering from a disease indistinguishable from the Hendon disease, but unaccompanied by any outbreak of fever amongst milk consumers. The general tone of Professor Brown's report is very adverse to that of the Medical Officers of the Local Government Board.

It will be admitted that the nature of the "Hendon disease" is now involved in the greatest confusion; but it must also be remembered that the observations made on the spot, and at the time, were those of Mr. Power, and that the conclusions come to by him are, therefore, worthy of the highest consideration.

3. *The Outbreak at Garnet Hill, Glasgow.*[2]—Dr. J. B. Russell presented a report in June, 1888, on this outbreak, of a most interesting and important character. During the last week in March a house-to-house visitation of the district was made; 1473 families were visited, among whom were 96 cases of scarlet fever and sore throat. The sore throat was specific, for it dovetailed in families with scarlet fever, the elders having sore throat, and the younger ones fever. The milk supply was enquired into: 172 families were supplied by dairy X, yielding 95 cases; 1301 families were supplied from other sources, yielding only one case. Outside this local area, the customers of dairy X at West End, Hillhead, and Kelvinside furnished many more cases of scarlet fever. In all, there were 189 cases—101 of fever, 88 of sore throat. Both diseases moved together, the earliest case of each being on March 15th, and the last being on April 1st and 2nd respectively. From March 20th to 25th, 74 persons sickened with scarlatina, 62 with sore throat. The cases after March 25th were mostly by secondary infection in the ordinary way. Mortality was very low, only one death being recorded.

Thus the milk from dairy X was the medium for spreading the disease. Whence did this milk derive its infectivity?

The milk came from three sources—A, B, and C. At the farms B and C everybody was in perfect health. At A there was a case of scarlet fever on the 23rd, and of sore throat on the 24th; at the dairy in Glasgow a case of each illness on the 22nd, and another case of fever on the 23rd; also two cases of slight sore throat among the distributing boys on the 26th and 29th March.

As none of these cases could have originated the epidemic, which began on 15th March, they must be regarded, as other cases, infected from the same source. The producers and distributors, being also consumers, themselves suffered.

The milk X not being infected through a human medium, the question arises: "Was it through a cow?" The stock at B and C were perfectly healthy. At A, on March 27th, Dr. Russell found in two cows appearances resembling those in the Hendon cows. The only recent additions to this stock had been one cow purchased on February 21st, and three on March 7th. One of the latter was thin and mangy-looking, *casting hair and shedding scarf skin;* the teats had several sores covered with bloody scabs. Of the other two cows bought at the some time one was sound, the other had one small scab on one teat. The cow bought in February had scabs also. Two of these cattle were removed to the Veterinary College, and observations were made there. It was recorded that a calf fed on the infectious milk was almost at once seized with a highly febrile illness which nearly killed it; and in recovering it lost hair and shed scarf skin copiously—*i.e.*, desquamation took place.

Now if we consider what are the various possible modes in which infection of the milk may occur, we have, I think, the same or similar four categories, as in the case of enteric fever—viz., (1) addition of water, to which the specific poison may have gained access; (2) contamination from the contagium floating about in the air, and falling into exposed surfaces of milk; (3) communication of the contagium, by personal contact with the milk, of individuals suffering from the disease, or convalescent from it, or in attendance on such cases; (4) some disease of the cow that is able to produce scarlatina in man. The second and third of these are probably the usual ways in which infection takes place, and considering the very mild character of some scarlatina cases (in which possibly a medical man is never called in), with slight fever, not much feeling of illness, and no very obvious rash, but still marked desquamation, and undoubted capability of transmitting infection, there will always be a considerable element of danger from this source. The fourth mode, from the cow herself, can hardly yet be said to be proved, although certainly Mr. Power's report on the Hendon cases does read almost as a demonstration; and Dr. Buchanan[1] says: "In the end he (Mr. Power) has demonstrated beyond reasonable doubt the dependence of the milk-scarlatina of December on a diseased condition of certain milch cows at the farm."[2]

Further investigations are required, and will no doubt be undertaken as opportunity offers. The communicability of the disease-poison from the cow is certainly possible—there is nothing impossible in it—though not proven.

[1] "Report on Eruptive Diseases of the Teats and Udders of Cows in relation to Scarlet Fever in Man." By Professor Brown. 1888.

[2] *Sanitary Record*, June, 1888.

[1] Report for 1885, p. vi.

[2] Since the above was written a review of Professor Brown's report has appeared in the *Practitioner* for March, 1889, evidently written by "one who knows." In this it is pointed out that the scarlet fever, referred to by Professor Axe as existing at Hendon, had been noted and reported on by Dr. Cameron, in his report for 1885, as "two mild cases—both carefully isolated, and disinfectants supplied. As the district is full of laundries, it is possible that the disease was introduced from London; there was no other evident source for it. The fever did not spread beyond these houses." Mr. Axe quoted this, but omitted to say that it was a quotation, made no reference to Dr. Cameron, and left out the last sentence. Professor Brown's deduction must therefore be received with caution.

The question is one of the greatest interest to all practitioners, and is stated by Mr. Power in these weighty words:[1]—"Few physicians will be disposed to deny a relation between scarlatina and certain forms of febrile puerperal disease in women. The contagion of scarlatina introduced into the lying-in room has often and with reason been held responsible for "puerperal fever." . . . . Now if it be true that there is one sort of relation between scarlatina and accidents of the puerperal state, another sort of relation becomes comparatively easy of belief; while there would be nothing improbable in the further suggestion that all such relations would be qualified by the passage of a common contagion through the system of another animal. . . . . If scarlatina in man have other animal source than human source, it may be that one such source is the cow that has recently calved, a cow either not at all ill (except for her parturition), or not so obviously ill as to prevent her milk being used for human consumption." And Mr. Power mentions three important facts:—(1) In epidemic outbreaks referred to milk as their cause, infectivity of the milk has commonly lasted a short while only—a week or ten days, according with some cow condition as well as any other suggested cause. (2) Such outbreaks have generally had relation to cow businesses that have had to do with the production of milk, and milk alone—not butter, nor cheese, nor calf-rearing—therefore the cows come into business use almost at once after calving. (3) Milk-scarlatina outbreaks have generally been characterized by mildness and small mortality. This is not inconsistent with an animal origin, not recently a human origin, of the infective poison, as in vaccinia.[2]

III.—DIPHTHERIA.

Of the seven outbreaks of diphtheria, particulars of which are related by Mr. Hart, the most extensive was one occurring in Kilburn and St. John's Wood in 1878, consisting of 264 cases in 118 households, with 38 deaths. The great majority of these households were supplied from one dairy, the incidence of the disease upon the customers of this dairy being twelve times as great as on the customers of other dairies. Most of the families were of the better class; no insanitary condition was common to the houses; no explanation could be given.

In another epidemic, at Weybridge, sixty persons were attacked during nine days, all supplied from one dairy; no insanitary condition common; no explanation. I have found other (seven) epidemics recorded since 1881, the best known of which have been those at Devonport, Hendon, Canterbury, Camberley, and Ealing. The connection between the spread of the disease and the milk supply seems established in all but one of these outbreaks (the exception being the outbreak at Putney in 1883, in which Dr. Blaxall discredited the milk theory), but the definite manner in which the milk became infective has not been ascertained. In the Hendon instance the milk cans were washed in a brook contaminated with sewage; a similar state of things prevailed in the Cardiff instance; and in two of Mr. Hart's cases (Weybridge and Addlestone) the water supply of the dairy farm was very impure. In two instances of Mr. Harts' (Kilburn and Addlestone), the disease of the teats called "garget" was considered to be possibly connected with the epidemic. In the Canterbury case, though the cows appeared healthy, four calves had diarrhœa; at Camberley Mr. Power found that one cow had chapped teats not unlike those of the Hendon cow disease. But from a consideration of these fourteen epidemics, it is not possible at present to say what is the manner in which the milk becomes infective, though that the milk was the infective agent in these cases, is in the highest degree probable.

It is to be noted that in most instances it was found that the better class houses suffered far more than the poorer class. Mr. Power suggests[1] that this is owing to the larger quantity of milk consumed, and to the practice of taking in a larger quantity at a time and keeping it for some hours—or "setting it" for cream—while the poor only take a little, and use it at once. In the Hendon outbreak the milk was found to be ropy, and was either returned or thrown away by some of the customers in consequence.

IV.—TUBERCULOSIS.

It cannot be said that the transmission of tuberculosis from cow to man by means of milk has been actually proved, as I think can be stated with regard to the three diseases we have just been considering. But in the nature of the case there cannot be any sudden or widespread outbreak which would draw attention to the connection between this disease and the milk supply, as happens in the case of those other diseases. There is, however, a large body of evidence tending to show that this transmission is possible, and considering the enormous prevalence of tubercular disease in this country, the importance of dealing with this question can hardly be overrated.

1. It may be regarded as proven that *tuberculosis can be transmitted* from the cow to other animals *through the milk*. Dr. Francis Imlach[2] made some experiments in 1883, by feeding healthy calves, pigs, guinea pigs, monkeys, and a goat with milk from tuberculous cows, but found no signs of the transmission of the disease, except in the case of the monkeys; and this could not be considered of much importance, as they are known to be exceedingly liable to it in this country. Other observers have, however, proved the transmission beyond a doubt, especially Gerlach and Professor Bang of Copenhagen. But it appears to be the opinion generally, as far as I can gather, that it is only the milk of cows suffering from tuberculous disease of the udders that is especially likely to give infection, and that unless this local manifestation of the disease exists, tubercle bacilli are not found in the milk, and infection is not transmitted. This was the opinion stated by Principal Walley at a meeting of the Edinburgh Medico-Chirurgical Society last year,[3] and appears to have been the general opinion at the meeeting of the British Medical Association last August (1888).

2. It is now admitted that *tuberculosis is exceedingly prevalent amongst cows*. The cows that are most affected are the stall-fed dairy cows in towns. Professor Fleming states[4] that 25 per cent. of such cows are affected; some

[1] Report for 1882. App. A. 9, pp. 66-67.

[2] In the report of the Medical Officer to the Local Gov. Board for 1887, dated August, 1888, but only just published (April, 1889), Dr. Klein gives the result of further researches, and, it must be allowed, strengthens his case, of the identity of the Hendon disease and human scarlatina as shown by their both being due to the same organism, considerably. He infected cows and calves with a streptococcus from human scarlatina; ulcers on the teats and desquamation of skin resulted. In some cases the same streptococcus was recovered from the blood and organs of these animals. He states positively, after long study of streptococci, that this organism is not what is generally known as S. pyogenes.

[2] *British Medical Journal*, 1884, ii., 175.

[3] *British Medical Journal*, 1888, i., 419.

[4] Quoted by Dr. L. Parkes, *British Medical Journal*, 1888, i., 847.

have stated even 50 per cent. At the Congress on Tuberculosis at Paris last year, it was stated that four out of every 100 cows were tuberculous.[1] Dr. Sims Woodhead[2] made a most careful inspection of over 600 cows in the Edinburgh dairies, with the veterinary Professor Macfadyean, and found thirty-seven beasts suffering from mammitis, but in only six of these could they demonstrate the presence of small numbers of tubercle bacilli in the milk, though these bacilli existed in enormous numbers in the udders. Granting that only milk from cows with tuberculous disease of the udder is infectious, 1 per cent. of dairy cows would be liable to transmit the disease. This, of course, is a very different thing from 25 or 50 per cent. It is no matter for wonder that dairy cows should be particularly susceptible to this disease, especially in town dairies. These places are often uncleanly, and nearly always ill-ventilated; the animal has no exercise, and is being drained of a large quantity of milk for a prolonged time. This prolonged lactation is known to predispose to phthisis in the human female. Even if only 1 per cent. of dairy cows are affected, as the milk of various cows is generally mixed, the tuberculous milk would be widely diffused. The presence of the disease does not lead at once to ill-health in the cow, loss of flesh, or diminution of the supply of milk. On the contrary, this latter is stated to be often increased; so that the disease may have existed for some time unsuspected.

3. The question of the *identity of bovine and human tuberculosis* has been answered in the negative by Klein, and in the affirmative by Koch, Bland Sutton, Watson Cheyne, Sims Woodhead, and others. Klein considers[3] that "the tubercular virus derived from the human subject is not exactly the same as that derived from the tubercles of the cow, because (*a*) the tubercle bacilli present in the human tubercles are morphologically different from those of the cow's tubercles; and (*b*) because, although the guinea-pig is susceptible in a similar degree to both the human and bovine virus, there is nevertheless a marked contrast between the two as regards the rabbit," which is not infected by human virus, but is very susceptible to that from the cow. So Dr. Klein wrote in 1883; and further experiments in 1885, which showed that fowls were susceptible to human, but not to bovine tubercular matter (*i.e.*, the opposite of rabbits), confirmed him in this belief.[4] In 1886, however, further experiments on fowls had a different result.[5] But the numerous observers just mentioned consider the two diseases identical, and this was considered as established by M. Chauveau,[6] the president of the Congress on Tuberculosis at Paris last year, and by several speakers at the British Medical Association at Glasgow, and may be taken to be the general opinion on the subject.

4. We have, then, these three propositions: I.—Tuberculosis can be transmitted from the cow to other animals through milk. II.—Tuberculosis is very prevalent amongst cows. III.—Tuberculosis in cows is the same disease as in the human species. We then come to IV.—Tuberculosis can *probably* be transmitted from the cow to man.

Professor Walley stated[7] at Glasgow that he had himself lost a child from mesenteric tuberculosis, under such conditions as to point to milk as the source of infection; and that within the past few years one of the officials of the Veterinary Department of the Privy Council had lost a child also in a similar manner; and, doubtless, several similar instances could be related.

In a paper on this subject in the *British Medical Journal* of April 21st, 1888, Dr. L. Parkes quotes the Registrar General's statistics to show that the mortality from tubercular peritonitis and tabes mesenterica, for the ten years from 1871 to 1880, in children under five years, was on an average 2.55 per 1,000 per annum—about the same as for measles (2.57), and more than twelve times as great as the corresponding mortality from these diseases at any other age-period of five years, from five to 100. "The extreme incidence of primary tubercular disease of the abdominal lymphatic system on young children is at once seen from these figures. In the matter of dietary, there is one great distinguishing feature between this age-period and all others. Under five years of age, milk—usually unboiled—forms the staple food of children."

EPIDEMICS OF MILK-DIPHTHERIA.

No.	Date.	Place.	Reporter and Reference	No. of Cases.	No. of Deaths.	No. of cases among drinkers of suspected milk.	Per cent.	Circumstances of Outbreaks.
1	1882 Dec.	Devonport	Dr. Parsons, L.G.B. Supp. for 1883	29	4	27	93	Origin unknown. Twenty out of the 29 cases were of adult age.
2	1883 Jan.	Hendon	Mr. Power, L.G.B. Supp. for 1883	62	..	?34	?55	Dairy utensils washed in brook contaminated by sewage. "Ropiness" of milk observed.
3	1883 April	Putney	Dr. Walker & Dr. Blaxall, *San.Rec.*, 1882-3, 515, 560 L.G.B. Supp. for 1883	17	5	17	100	Out of 400 families supplied with suspected milk, nine were attacked Diphtheria had prevailed in the district previously. Dr. Blaxa doubts whether milk was the cause.
4	1883	Cardiff	Dr. Paine, *B.M.J.*, 1883, i., 973	..	..	..	..	Polluted well at dairy.
5	1886 July	Canterbury	Dr. Wacher, *B.M.J.*, 1886, ii., 397	231	0	..	..	231 cases of local throat inflammation, with white patches on tonsils, and enlarged cervical glands, occurring within eight days. Out of 120 houses in which cases occurred, 94 were supplied with one milk.
6	1886 Oct.	Camberley and Yorktown	Mr. Power, L.G.B. Supp. for 1886	135	16	124	92	Incidence of the outbreak much more on better-class houses than on the poor, larger quantities of milk being taken, and stored before use.
7	1887 Jan.	Ealing	Mr. W. H. Power, L.G.B. Supp. for 1887, *B.M.J.*, 1887, i., 292, 342, and ii., 156	30	12	28	93	Sudden small outbreak of diphtheria during seven days, affecting solely customers of particular dairy. Before this, and subsequently, many cases of "sore throat" mainly affecting families supplied from this dairy. Connection "not proved."

V.—OTHER DISEASES.

1. *Throat Illness* in connection with *Foot-and-Mouth Disease*.—In 1884, at Dover,[8] there suddenly broke out an

[8] *British Medical Journal*, 1884, vol. i., 627. See also a paper by Mr. Francis Vacher, in the *Sanitary Record* for September, 1881, p. 89, in which he relates three cases of this disease transmitted by milk, and refers to records in the *Veterinarian* for 1841, and the *Veterinary Review*, iv., 502, and v., 187.

epidemic of sore throat, with shivering, headache, some fever, with vesicular eruption of the throat or lips, enlarged tonsils (afterwards suppurating in some instances), and in most cases with enlargement of the glands of the neck. These symptoms resembled the aphthous fever of cattle, or foot-and-mouth disease. There were 205 cases in the week ending February 9th, all but eight above seventeen years old, all supplied with milk from one dairy, but living in different parts of the town, and with no other common condition but that of milk supply. It was ascertained that foot-and-mouth disease existed at one of the farms from which this dairy derived its milk.

In March of the same year, 1884, at East Dereham,[1] were many cases of throat illness among children, with some deaths, apparently due to milk from cows suffering from the same disease.

Mr. Hart relates[2] the case of the Aberdeen epidemic of 1881, where 300 persons were attacked with illness, the symptoms being rigors, fever, slight enlargement of tonsils, but no false membrane, and a marked feature in the illness being enlargement of the lymphatic glands of the neck, and those above the clavicle. The febrile symptoms passed off in a few days, but there were often relapses. The dairy, whence the milk supply of all the cases was derived, was attached to a Reformatory School, the boys of which got skim milk, and entirely escaped. The officials got sweet milk, but only a few were affected. With the stoppage of the milk supply, the disease ceased. The water supply of the dairy was bad. No explanation was given of the outbreak. The symptoms seem to have resembled those in the Dover outbreak, attributed to *eczema epizoötica*, or foot-and-mouth disease.

An outbreak of sore throat occurred in an institution in Edinburgh in 1888, on which Dr. Sims Woodhead and Mr. Cotterill read a paper before the Edinburgh Medico-Chirurgical Society in June (see *British Medical Journal*, June 9th, 1888). The milk supply was suspected; it was stopped, and the epidemic ceased. The milk was again taken into use, and the epidemic re-commenced. Lastly, the milk was boiled, and no further cases occurred. Dr. Woodhead found various organisms to be present in the milk. Many of the cows showed signs of cow-pox.

2. *Gastro-enteritis.*—At the Societé de Medicine Publique in Paris, in November, 1885, M. Toussaint[3] brought forward facts from the death-register returns, showing that deaths from gastro-enteritis, and from intestinal affections, were more common among bottle-fed children in the district of Argenteuil, since a large distillery had been established there, the cows being fed on brewers' grains, and the milk being acid.

3. *Poisoning.*—Surgeon R. H. Firth relates[4] an instance of poisoning among troops at Mean Meer in August, 1886, the cause of which was traced to the drinking of some milk that had apparently been kept in a dirty pan. The symptoms were "nausea, vomiting, dryness and intense constriction of the fauces, vertigo, colic, purging, and in some a tendency to collapse: in others, numbness of the extremities, and a tendency to stupor." Under simple treatment all the cases recovered. On treating some of the milk, after coagulation, with potash and ether, and evaporating, a moist semi-crystalline residue was left, with a sickly odour, which on application to the tongue caused sharp pungent taste, nausea, dryness of the throat, and headache. Mr. Firth subsequently obtained the same, or a similar body, from good milk that had been kept for a long time. He considered it a ptomaine, and named it *lactotoxine*.

Professor Victor Vaughan, of Michigan, relates[5] some cases of poisoning from eating "sick" cheese, the symptoms being dryness of the throat, nausea, vomiting, diarrhœa, nervous prostration, headache, and sometimes double vision; the symptoms, in fact, of a gastro-intestinal irritant, with marked effects upon the nervous system. Recovery generally follows, though death has occurred in rare cases. After much trouble, he succeeded in isolating the poisonous principle by rendering the aqueous extract of the cheese alkaline with potash, and then extracting with ether. Needle-shaped crystals were formed, which, placed on the tongue, gave a burning sensation, followed by dryness and constriction of the throat, and nausea, the taste very sickening. He named the poison tyrotoxicon, and considered that it belonged to the class of ptomaines. He found also that it developed in milk after long standing in closed vessels. He found that from cheese containing this poisonous matter, when freshly cut, there always exuded drops of a watery opalescent fluid, which reddened blue litmus paper instantly and intensely. He considers that any cheese giving this instantaneous and intense reaction is suspicious. The symptoms of poisoning, and character of the poison in these two cases, appear almost identical.

Cases of poisoning from ice cream, sold in the street, have frequently been recorded, but, as far as I know, the actual toxic agent has not been discovered. Cases of poisoning from the milk of cows afflicted with the "trembles," supposed to be produced by their feeding on *Rhus toxico-dendron*, have been recorded from the Western States of America. In this "milk-sickness" in children there is weakness, vomiting, fall in temperature, dry and swollen tongue, and constipation. Boiling removes the poisonous properties. At Malta, diarrhœa has resulted from drinking the milk of goats that have fed on Euphorbiaceous plants.

4. *Cholera.*—Dr. Simpson, Health Officer for Calcutta, in his report for the first quarter of 1887, related[6] the particulars of a slight outbreak of cholera and choleraic diarrhœa on board the ship *Ardenclutha*, lying off Calcutta, resulting in nine cases and four deaths, in which the poison seemed undoubtedly to have been conveyed through milk. Of the crew of this ship, those who drank milk brought by a particular native milkman, all (with one doubtful exception) suffered; and no one who did not drink the milk was attacked (with one doubtful exception). The milkman was traced, and was found to live near a tank into which dejecta from a cholera patient found access; and he confessed to habitually diluting his milk with one quarter water from this tank. All other likely causes were enquired into and found negative, before this apparently clear causative connection was discovered.

CONCLUSION.

The practical question that we have to answer, from a consideration of these dangers in our milk supply is, How can they best be prevented or minimised? The measures necessary or advisable may be conveniently considered under the two heads of (1) those applicable to the milk

[1] *British Medical Journal*, 1884, vol. i., 575. [2] *Loc. cit.*

before it reaches the house of the consumer, including the inspection and management of dairies, dairy farms and milkshops, which is a matter of Public Health; and (2) the best thing to be done by the consumer in his own home, to make sure that neither he nor his family shall run the risk of "catching" anything through the milk supply.

1. It was mentioned at the beginning of this paper, in regard to typhoid fever spread by milk, that the infection might occur conceivably in four ways:—(*a*) By addition of water to the milk containing the specific contagium; (*b*) by the specific contagium gaining access from the air to exposed surfaces of milk; (*c*) by communication to the milk of the contagium from a person engaged in the distribution of milk, either ill himself, or in attendance on someone ill with the disease; (*d*) possibly there may be disease of the cow that can be transmitted to the human subject through the milk. The spread of the other specific diseases mentioned may take place in like manner.

(*a*) By punishing adulteration with water, the first channel of infection can be in part closed to the intrusive germ; but only in part, as water used in washing cans *may* contaminate the milk. Careful inspection of the sanitary conditions of the dairy, and provision of a pure water supply are here indicated. As regards (*b*) and (*c*), we have the 9th Section of the Dairies, Milkshops, and Cowsheds Order of June 15th, 1885, which makes it an illegal act for any trader in milk, either himself or his subordinates, to have anything to do with its distribution "when suffering from a dangerous infectious disorder, or having recently been in contact with a person so suffering." The execution of this order is now vested in the sanitary authority, and when the new County Councils are fairly started, we may expect (as there is room for) a progressive improvement. But still there will always be the possibility of mild cases of scarlet fever, or diphtheria, or typhoid being unrecognised, or only recognised when the mischief has been done. (*d*) The careful inspection of dairy stock by skilled veterinarians will doubtless tend to prevent the fourth source of infection. This is especially important as regards tuberculosis, and most especially tuberculosis of the udder.

2. But even if everything is done that can be done, there will still be the possibility of infected milk reaching a household. In that case what should an ordinarily prudent man do, not one who is full of fads and crochets, and always on the look-out for fancied dangers, but the sensible man who keeps his water closets in good order, sees to the purity of his water supply, and tries to keep his house and its surroundings in a wholesome condition? Fortunately, the precaution to be taken is of the simplest possible character: it is merely to *boil all milk before use.* This does not mean placing a jug of milk in a saucepan full of water, and just bringing the latter to the boil for a moment or two; but it means that the milk itself should be brought up to 212° F. for four or five minutes. If this be done, we have every reason to believe that no specific contagium will retain its vitality, and the milk may be drunk with safety.

It must be admitted that even now we are not armed at all points to repel every possible attack of the supposed invading germ; we can boil our milk, but we cannot boil our *butter* or our *cream.* There is nothing in the making of butter that can be considered as doing away with the possibility of the presence of the specific contagium in it, supposing any to have existed in the milk; but I am unaware of any record of disease traceable to butter, or even of any allusion to the possibility of such an occurrence, though I have searched through a considerable bulk of literature bearing on the subject. For the present, we must be content to eat our butter in fear and trembling; and with regard to cream, if we indulge in the luxury, we must be content to take it "all risks included."

FOOD AND DRINK.

By E. Bonavia, M.D., etc.

(*Continued from p.* 338.)

Supposing, however, that the misery from drunkenness is what it is estimated to be, is that any good reason for endeavouring to stop the use of alcohol among a whole population? Probably a single year would show more broken heads and limbs, and misery from railway collisions, and other accidents than from the abuse of alcohol. Would that be a sufficient reason for endeavouring to stop all railway travelling? One might as well try to prohibit the use of fire, because now and again a conflagration occurs with great destruction of life and property. And yet probably on account of the very want of alcohol, total abstainers may be *unable* to see the absurdity of their arguments.

If I might venture to suggest a useful field for research for the philanthropy of any association, here I think is one. The deaths from fever in the North Western Province of India and Oudh in the sanitary report for 1883, are put down at 830,258, or 18.82 per 1,000 of population. Here is a sufficient amount of misery in one part of India, in one year, for an association to sympathise with. The vigour of the whole population appears to be lowered. A sufficiency of food and quinine is not enough in certain climates, and the people cannot withstand what are called malarious influences, originating from alternations of temperature, and the consequences of fever, such as enlarged spleen, anæmia, liver complications, etc. No amount of quinine or cinchona febrifuge is able to cope with this misery. I have a strong suspicion that this mortality from fevers and allied diseases is due to a restricted use of alcohol, and that a more extended use of this important drug, among villagers, would perceptibly decrease the mortality from this cause, by raising the standard of nervous endurance of the population. There might result a few more broken heads, such as occur in the "Holi" festival, but what would a few broken heads be in comparison with thousands upon thousands of deaths from fever, and consequent misery to innumerable families! I could not of course prove all I have stated. It would require a life time to do so, but it might be very instructive to find out whether among the castes, who use liquor habitually, such as *kaiths*, *kahars*, *chamars*, *dhobis*, *kunjurs*, *mehtars*, etc., deaths from so-called fever are less than among abstainers.

One might say that the use of alcohol is not prohibited among natives—not by law of course, but *certainly* by their purse. All the poor people say that they cannot afford to purchase any *sharâb*, either when they are well, or when they are sick. Who can tell how many linger and die after fever from weakness, just for the want of a few mouthfuls of stimulant every day. I am informed that in the Etawah district, for instance, villagers can only get liquor where there are licensed vendors. It is said that in no case, however, have they to go more than five miles from their homes for it! By no means is this a

short distance for a weak person to walk in a hot climate! Liquor of only one strength is sold at the Government "godown," at Rs.3 12s. per gallon. Then the vendors dilute it again. The retail dealers sell the diluted liquor at either sixteen, fourteen, or ten annas per ordinary quart bottle. It is said, by those who are in the habit of drinking, that one bottle at twelve annas would be enough to make two of them unfit for work. That a quarter of a bottle taken by a man, unaccustomed to it, would unfit him for work. And that one *chatank*, or two ounces, would only make a man, unaccustomed to it, *comfortable*. Natives have two terms for expressing the degrees of alcoholic effects—one is *nashà*, which means that the effect of it is so far felt as to make a person bright and loquacious, with a warming up of the skin. The other is *matwàla*, which means that the person lies down unfit for work and helpless. Out of Etawah, I am informed, there is not much drinking, except at the "Holi," and at weddings, etc., as not many are seen drunk. The truth I fancy is, that, supposing the average value of a labourer's day to be represented by two annas (the hire of a coolie for a day) there can be little left out of this threepence for purchasing liquor. He requires at least one anna to feed himself; the remaining anna is for feeding his wife and family, and for clothing them and himself, although their wardrobe is not very extensive. Of course, two annas would not suffice for them. The way they manage to make both ends meet is this: The main crop goes to pay the rent. They live on the balance of their fields, which is the cheapest, and therefore the least nourishing, kind of grain. The wife, in the time she can spare from grinding, cooking, and making "*ooplas*," helps to make a bit of clothing, and by exchanging some of their grain, they manage to get up a wardrobe. The children go out hunting for cow-droppings to supply fuel for the pot. The husband has often to build or repair his hut, attend to the field, etc. The reader can easily understand that out of the average earnings of the villager, absolutely *nothing* can remain for spending on liquor. A bottle of liquor, at twelve annas, contains twenty-four ounces, and therefore two ounces, which is said to be the minimum to make a man, unaccustomed to it, comfortable, would cost one anna—a daily sum which is out of the reach of the generality of the rural population. Of course, at weddings and the "Holi," "*coute que coute*," the villager borrows money and makes himself merry. Unless well-to-do, the people of a village have never a fund of energy in their system. They are never more than just barely nourished, and very rarely stimulated. They have not even the solace of *coffee* like the Turks. When, therefore, unhealthy times come, and fever and other ailments prevail, the villager easily falls a prey to sickness, and if he do not actually succomb, he often lingers with enlarged spleen, anæmia, and general debility. Total abstainers might say: If, as you surmise, the villagers want of bottom is the cause of fever, it is better that he should die of fever, than of a broken head, from drink. This, however, would not meet the question.

The Sanitary Report for 1883 further states that the mean ratio of deaths from the same causes for *previous* years is 26.22 per mille. How much the decrease in recent years is due to a more extended use of alcohol, I do not know. Probably some portion of it is due to better sanitation, although the rural districts, I dont think, have been much affected, by modern sanitation. That there is any connection between an annual high mortality from fever, and a low consumption of alcohol is only a surmise of mine, drawn from cases that came under my treatment; from their history, and from inquiries that I have made. But irrespective of fever, it can hardly admit of a doubt that the population of India is *generally* under-alcoholed. A proof of this can be obtained from the statistics collected by the Bengal Excise Commission. A review of their report appeared in the *Pioneer*, of June 9th, 1885, page 2. The report states that "in 1875-76, the out-turn of proof spirit was from 1,434,623 to 1,763,095 gallons; and in 1883-84, it was from 3,381,244 to 4,131,832 gallons." . . . "That under the influence of cheaper liquor, better wages, and more regular employment for the lower classes, drinking should increase is a matter of course." Notwithstanding this increase, the reviewer goes on to say, "but even the estimated consumption is not excessive. The highest estimate gives to each *professed drinker* less than a pint bottle of spirit in the month, and the lower estimate about a third less (!). And it has to be rembembered that the estimated number of drinkers is a low one, and that in India a large proportion of the consumption of liquor takes place on special occasions, when many people, who are not regular consumers, take their share. The consumption per head of the population is infinitesimally small, amounting, even according to the highest estimate, to only $\frac{1}{16}$th of a gallon in the year" (or 10 ounces per head of population per annum!) That is if all the spirits made were distributed equally among every member of the population, each would only get 10 ounces of spirits in the whole year. As little less than this can be drunk by each person at the "Holi" and weddings, there can be little doubt that during the rest of the year the generality of the population get *nothing*.

Recently in the Etawah district there was a sort of epidemic of quarrelling, and breaking of heads. I especially asked one of the deputy magistrates, whether alcohol had much to do with it. He said he lately had four cases running, in which alcohol had nothing whatever to do with the quarrelling.

Relation of Diet to Climate.—Now let us contrast the feeble villager of upper India, which in winter has a bracing climate, with the "*Masula*" boatman of Madras, a place, which is hot, even in winter. There is a wrong notion, which unhappily has crept into some scientific books, that people in the tropics eat little else but rice, because naturally it is the only diet which is good for them! The "*Masula*" boatmen of Madras are *perfect* types of strength, muscular development, and general good health. A few years ago I stood looking at them with astonishment. They were landing passengers and luggage at the pier. The muscles of their neck, their trunk, their arms and legs—all had a marvellous development—such as is not seen out of a circus, or a band of acrobats. I asked a native who spoke English, and knew them, what they ate. He replied plenty of mutton or beef, according to religion; plenty of rice and vegetables; and they drink plenty of "*arack*," which comes from Colombo. There are among them Mahomedans, Hindoos, and Christians. They live either in, or on the water. Here is a nut for anti-liquor, and anti-meat associations, and scientific men to crack. A set of men only thirteen degrees or so north of the Equator, living *habitually* on meat, vegetables, and alcohol, and doing *hard work*. This is evident from the fine development of all the muscles of their body. They are more like navvies, and are infinitely superior in vigor and whole build, to the Northern Indian, who is, as a rule, strictly a

vegetarian (milk excepted), and practically a total abstainer. I had not time to make further investigations, or I should have tried to discover whether the *Masula* boatmen are often ill. They certainly did not look like men who were subject to much illness. However, in order to make sure of what I said regarding the diet of these athletes, I wrote to a friend in Madras, an engineer, and a good mathematician, to make further enquiries about the mode of life of these wonderful men. Being a scientific man, his statement is likely to be perfectly reliable. He writes: "the *Masula* boatmen are about 400 in number, the most part being Hindoos, principally Chettias, and the remainder Roman Catholic Christians, with a small sprinkling of Mussulmans, who are recent importations from Cuddalore and Negapatam. Their average height is 5 feet, and weight 150 pounds. This seems high, but I believe it is from actual experiments. They rise very early in the morning, and go to bed by 8 in the evening, unless they work over-time. In ordinary times, they earn about 8 annas a day. Their food consists mainly of rice, of which they eat two ollocks (raw measure), at each of their three daily meals, with curried mutton, fish, vegetables, *dâl*, or curds and whey. The quantity of meat they eat depends on what they can afford, but they usually do not get much, as fish is cheaper. The Christians among them eat pork, but none of them admits that he will touch beef (perhaps a survival of Hindoo feeling). There are no pure vegetarians, nor are there any teetotalers among them. Their drink depends on their earnings. When work is slack, they drink toddy, of which none says he drinks less than two measures a day (a Madras measure is about a quart). When flush of cash, they drink arrack (fermented toddy), three to five drams per man, per day. Their health is usually good, and I could not find that they are much subject to the complaints you mention (fever, enlarged spleen, and anæmia). When a month off the water, they are said to get ill (probably from want of exercise). They of course anoint their bodies with oil, for work in the water. They begin work at eight or nine years old, first fishing, and afterwards boat work."

My *syce*, who was an expert in the matter of drink, said: one quart bottle of fresh toddy (târee), drunk by a man not accustomed to alcohol is only enough to make him *khoosh* (comfortable). But stale toddy (arrack), he says, is much stronger. I fancy fresh toddy is like *very light beer*. It is also considered nourishing. It should be understood that people in Bengal and South India do not eat rice because they think it the *best thing* for them, but because it is the *cheapest* grain, wheat being probably *unobtainable*, by the poor classes. As rice has only $7\frac{1}{2}$ per cent. of nitrogenous matter, while wheat has 20 per cent., rice eaters have to consume about three times more of it than they would of wheat. Europeans, seeing large masses of rice before the natives, have jumped to the conclusion that they eat rice because it is the best thing for them, and that they eat little else in a hot climate—no greater delusion. They eat rice because they cannot get wheat, and when they do eat it, they must consume a larger quantity of it, and make up by fish, meat, *dâl*, or curds.

On one occasion I employed, for several months, a silk-reeler in Lucknow—a thin, miserable native of Bengal. He was in the habit of eating a good deal of rice, and could get as much as he liked of it in Lucknow. But he once tried wheaten *chapatties*, and he liked them so much that he gradually dropped the rice and stuck to the *chappaties* and *dâl*. He thrived so well on the wheat that when he left he was a different man, and said he would have some difficulty in going back to the rice diet when he returned to Bengal. Bengâlis, although they consume rice largely, eat also a great deal of fish and dâl. And it would be as accurate to say that they live on almost nothing but rice, as to say that the English live on almost nothing but *beef*.

Now with the *Masula* boatmen of Madras I shall compare three first-class prisoners in the jail which was under my charge. They were inhabitants of the N.W. Provinces. They were all five feet high, and were on hard muscular labour. All had increased in weight since they came into jail.

	md.	s.	ch.		md.	s.	ch.
No. 1 weighed	1	12	8	On admission weighed	1	9	5
,, 2 ,,	1	7	0	,, ,, ,,	1	6	12
,, 3 ,,	1	10	12	,, ,, ,,	1	4	14
	3	30	4				

Or an average of 1md. 10s. 1ch., which corresponds to an average of about ninety pounds or so.

The daily diet of the first-class prisoners consisted of eleven ounces of wheat, about seventeen ounces of grain or millet of different kinds. Four times a week in addition they got four ounces of dâl; and on the remaining three days twelve ounces of vegetables. These weights are for the uncooked materials, and the above amount was divided into two meals. They also got one chilly, thirty-six grains of oil, and 100 grains of salt per day, and in the hot weather and rains some vegetable acid. They got no meat or fish, no alcohol, tobacco, or opium. Of course, I could not swear that no prisoners ever got a smoke. Every day they were let out by the sound of a gong early in the morning; recalled by gong in the middle of the day for their dinner, and again in the evening for their supper. They were locked up at dusk. They had a mat to sleep on; their beds, although of dry clay, were raised, and they had plenty of ventilation. In summer they had only light cotton clothing, and one blanket if they cared to make use of it. In winter they had in addition a woollen coat, a woollen cap, and another blanket. Most of these prisoners, provided they were a certain time in jail, increased in weight, and usually those who worked hardest gained most. In short, these prisoners were so well cared for that probably no villager, who had not been fortunate enough to get into jail, had ever been similarly cared for, from the day of his birth to that of his death. I should mention that these prisoners by a mistake of mine had been getting a little larger proportion of wheat than they were entitled to by the rules; yet with all this care and feeding the average weight of these three was only ninety or a hundred pounds!

Whoever would wish to learn how various the needs of man are under different circumstances, and what is good for him to eat and drink in the tropics, in order to keep himself in health, might do worse than get a lesson and disabuse himself of notions inculcated by books by questioning those athletes—the *Masula* boatmen of Madras. A finer and more muscular set of men cannot be found. As has been already stated, they eat rice, meat, fish, *dâl*, vegetables, etc.; drink a good deal; work hard and sleep *sufficiently*. Of course they have no desk work or other mental worry, and live in the open air.

Depend upon it, if people in Europe would cease to write and talk from their own imaginations and would go over the world and see "with their own eyes" (seeing is believing) what this animal man looks like in different

countries, what he feeds on, what he drinks, and otherwise takes, how much he sleeps, what work he does, how long he lives, what he is capable of, what diseases he is subject to, with a few other simple details, and examine themselves, and feel with their own skin what Europeans have to endure, who belong to a totally different climate and race, and have invaded the whole world, they would be able to write more practical books on dietetics, hygieny, and physiology in general than are to be had at present. Persons who possibly may have not left their studios in England, write books with an infinity of microscopical details, and with a bewildering multiplicity of new names, and yet go on copying from each other's books antiquated notions about people in the tropics eating little but rice, and that alcohol is not good for them.

To show that I am not writing at random, I shall quote from books. Carpenter's physiology, edited by Henry Power, M.B., F.R.C.S. (anatomist and physiologist), ninth edition, published in 1881. At page 99, he says: "And we find the Hindoo adding his modicum of 'ghee' (or rancid butter made from bison's milk) to the rice, which constitutes his staple article of diet, with the same relish that the Esquimaux feels for massive lumps of blubber." In this quotation there are two, if not three, errors. First, "ghee" is made out of the butter of the buffalo, the cow, the sheep, or the goat, but no one has ever heard that in India it is made from bison's milk. Secondly, there are many Hindoos who rarely eat rice. Rice eating in India is a matter of comparative cheapness; and certainly in Northern India it is the exception and not the rule. Thirdly, *bazar* "*ghee*" may be rancid, and is often anything but butter, but good "ghee" made at home is not rancid. Moreover, many Hindoos never eat "ghee" simply because they cannot afford it.

Now leaving out of calculation the Mohamedan population, who are intermixed with the Hindoos, *all over India*, and who are *meat* eaters, it is as accurate to say that *rice* constitutes the staple article of diet of the Hindoos, as it is to say that *porridge* is the staple article of food of the people of Great Britain. Over and over again have I read in scientific books that the Hindoos live upon little else but rice. Here are two prisoners, both Hindoos, taken at random, whom I questioned about home food, at the time I weighed them, after conviction.

(a) A *Dhânuk*, 5 feet 1½ inches high, 105 lbs. weight, a strongly built man. He says he eats pork, mutton, fish, wheat, and dâl. *Rice he eats once or twice a month.* He drinks spirits at "Holi" time and weddings. He gets two annas a day, and has himself and his wife to support. He is a habitual thief.

(b) A *Bunyà*, a strong fellow, five feet six inches high, and weighs 130½ lbs. He says he never touches spirits. He eats wheat, dâl, and other grains. *He eats rice from ten to twenty times a year.* He is imprisoned for culpable homicide. If he had not been a teetotaler, his crime might have been attributed to drinking. On page 108 of the same book I quoted is the following: "Fourthly, the special liability of the intemperate to zymotic diseases, seems an indication that the habitual ingestion of alcoholic liquors tends to prevent the due elimination of the azotized products of the disintegration of the system, and thus to induce a "fermentible" condition of the blood." Books on the practice of medicine also state that intemperance renders persons liable to get yellow fever. Yet we have been told that in a recent epidemic of yellow fever (a zymotic disease), in Bermuda, among the few who did not get it, were those who were habitually intemperate. So much so, that these were the only persons, who could be got to go near the sick, or bury the dead!

Further on, the following occurs: "On these grounds, the author has felt himself fully justified in the conclusion that, for physiological reasons alone, habitual abstinence from alcoholic liquors is the best rule that can be laid down for the great majority of healthy individuals, the exceptional cases, in which any real benefit can be derived from their use being comparatively few." Now is this theory founded on *real facts*, collected all over the world, where man exists, or is it evolved out of the writer's imagination, biassed by *Temperancism*? Another book—a recent publication—the "Book of Health" at page 167, states that "the Sicilians and many of the natives of Southern Italy, live almost entirely on bread, or macaroni, which is practically the same thing with a little fruit, or other vegetable." That "almost entirely" (like the all rice diet of the Hindoos), covers a delusion, and is a loose way of writing in a scientific work. The Sicilians and Southern Italians, it is true, eat a good deal of maccheroni and bread, but they also eat a good deal of fish (including "*baccala*" or salted cod-fish), lamb, tripe, liver, fried blood, eggs, milk, cheese, "*ricotta*," fruit, lentils, haricots, beans, mushrooms, olives, oil, lard, etc., besides sausages, ham, bacon, and numbers of other "*Pizzicherie*." They almost all drink coffee (now adulterated with chicory), and I should say there is not a "*teetotaler*" among them. On Sundays and festas, and market days, unless they are beggars, they invariably have either beef, pork, fowl, or such like extras, and on these occasions they have *meat gravy* on their maccheroni; and there are probably few who eat maccheroni, without sprinkling a good deal of grated cheese over them.

Some other facts may not be without use, to show that alcohol is an important item in keeping up the general tone of the nervous system, more especially in hot climates, and when taken habitually and in moderation. No doubt its usefulness depends upon the dose. All physicians well know that a drug given in different doses is followed by different effects. Opium in one dose may be a tonic, and stimulant; in another, a narcotic; and in a third, a poison.

Sir Samuel Baker in his travels through Central Africa, proved the value of alcohol in fever. After the store of quinine had come to an end, and not having any spirits, he devised a still, and made a sort of whisky from the fermented grain of the country. By this alcoholic drink, he saved his life, and that of his wife.

(To be continued.)

ON THE TREATMENT OF THE ACUTE STAGE OF ECZEMA.

By D. Mackintosh, M.D., C.M.

The literature of eczema is pretty extensive, and it can hardly be contended by the most astute observer and exacting critic that owing to the prevalence and importance of the disease its treatment has not received a corresponding share of attention. It must indeed be conceded that more than ordinary attention has been bestowed upon the subject. Numerous remedies and modes of treatment have from time to time been suggested for the benefit of sufferers from this troublesome complaint; and, although I have nothing very new or original to communicate, I have suggestions to make and remedies to propose which in the aggregate will speedily arrest the inflammatory stage of the disease, and

put an end to perhaps months or years of future suffering. Had the remedies proposed been less numerous, confusion in their selection and application would have vanished in like proportion. A good deal has to be laid to the charge of those whose mission it is to add to our accumulating stock of remedies. What the busy practitioner of medicine requires is not a multiplication of medicines, many of which are of equal value, but a judicious selection ready to hand and for use on which he may place reliance, and with which he may cure his patients in the shortest possible time both for his own reputation and their benefit. What applies to medicines equally applies to books. A little farrago of remedies is more often than not laid down in the chapter on treatment for the practitioner to select from; instead of the best being pointed out or selected for him, he is left to grope about in the dark, and wade through the mire of remedies the best way he can. My contention is that the experience of bookmakers, and those giants in physic that have gone before ought to be made to lead the junior and less experienced members of the profession in the selection, and mode of administration of the most suitable remedies under, if possible, every conceivable circumstance. I have at my elbow an otherwise excellent volume on skin diseases, where no less than forty-nine drugs are mentioned *seriatim* by an eminent author for external use in eczema without note or comment as to their relative value. This is not at all the sort of book the busy practitioner requires, it is of no practical utility to him. He scans its pages in vain for the benefit of patients to be seen on the morrow's rounds, or expected in the consulting-room in a few minutes time. He is forsooth obliged to lay it aside in the forlorn hope of gleaning nothing of practical advantage from its columns. We want to make ourselves and our books as practical as possible. All knowledge is useful and desirable, but let us more particularly study that description of knowledge which is not scattered over too wide a field for practical purposes —the knowledge that tells in a particular direction—that we daily require at our finger-ends—that leads to the cure of our patients, and is creditable and advantageous to ourselves. Less of theory and more of the practical is the order of the day. The public estimate of us will be none the less favourable if they find us alive to our own interests as well as equal to the emergencies for which our opinions are sought. The probability is that the estimate is rightly formed that is based on the successful application of our knowledge, or on the other hand on our random hits and failure. Our patients believe in us under the former *regime;* we don't see them long under the latter dispensation. The most suitable prescription to our patient at the first interview is urgently demanded. That forty-nine remedies may be indicated in a particular disease, we may with a stretch of imagination believe; but that a particular patient will present himself at our consulting-room forty-nine times to be experimented on with a fresh prescription every time is rather problematical.

In the treatment of the acute stage of eczema, two essentials must be reckoned with before we proceed to tackle the disease itself. The first of these—the patient must be instructed not to wash the eczematous parts, and this advice he must religiously observe. He will probably reply, "but I must wash sometimes." Wash not at all is the new gospel in eczema. He must neither wash with, nor yet without, soap, nor with the usual adjuncts of bran steeped in hot water, oatmeal, milk and water, butter-milk, whey, sour-milk or rain-water, or any other of the usual washes, all of which are mistakes that seriously hamper and delay all curative treatment. That persistent washing predisposes to eczema by drying up the skin and depriving it of the unctuous secretions which impart to it suppleness and softness, qualities on which the natural beauty of the complexion so largely depends, there cannot be a doubt. For the same reason and in the same manner, although it is not generally known, frequent washing with soap and water is disastrous to the growth of hair; it changes its natural colour to a lighter hue; the natural gloss is lost; the hair becomes dry and prematurely grey and early baldness is favoured. The process of destruction is materially hastened by washing the head with warm or hot water during cold weather. The hair and beard should be dressed and kept clean by combing and brushing; a process all-sufficient for purposes of cleanliness, and the only method for preserving a fine head of hair.

In eczema of the head and face, the more essential parts to wash, such as the corners of the eyes and angles of the mouth, may be touched lightly with a small piece of soft sponge, made damp with cold water and immediately dabbed dry. Warm and hot water should be discarded even in the neighbourhood of the eczematous skin. A patient suffering from eczema of the head and face only, may of course sponge and wash his body with warm water as frequently as necessary. Coffee, strong tea, and alcoholic drinks should be forbidden.

The second indication is that the bowels be kept well open. The advantages that are derived from "keeping the ports open" are as apparent in the treatment of eczema as they are substantial and well-understood in political economy. In the case of children grey powder, rhubarb, and soda bicarb, in the proportion of a grain of each taken as required every second or third night, will answer every purpose, or grey powder and magnesia will do equally well. In adults saline medicines hold the first rank taken at regular intervals during the day. The following combination is useful:—

℞ Magnes. sulph..... ℥ vj.
Sodii bicarb..... ℥ j.
Infus. gentian. co.... ad ℥ viij.
M. Take an ounce three times a day before meals.

The sulphate of magnesia is, far and away, the best of all purgative medicines in most other diseases as well as in eczema; the best because the mildest; the least irritating, and certainly one of the most effectual; but it must be taken at the proper time and in the proper quantity. The proper time is an hour before meals, preferably in the morning before breakfast, although it may be taken before any other meal with nearly equal benefit. The proper quantity is three drachms, dissolved in three parts of a tumbler of cold water, or soda water. Hot water does not materially help its action, and it makes the drug more nauseous. Three drachms, sulphate of magnesia, dissolved in an ounce of chloroform water can be "toppled over" almost without taste or inconvenience if followed directly by a cup of tea or beef tea. A four or five grain blue pill taken at night, and the same draught next morning, has its advantages. What is perhaps better still when free purgation is desired is the following pill at bedtime, and the draught in the morning?

℞ Ext. coloc. co..... gr. iij.
Pil. hydrarg..... gr. i.
Ext. hyoscyam. .... gr. i. ft. pil.

Where there is evident torpidity of the liver, the following combination is equal, if not superior, to any other :—

℞ Ext. cascar. sagrad. liq.. ʒ iiiss.
Tinct. nuc. vom. ..... ʒ i.
Glycerini ..... ʒ iij.
Infus. gentian. co. ..ad ʒ viij.
One ounce to be taken directly before dinner, or morning and evening if required to keep bowels regular.

Such medicines as arsenic and iodide of potassium given internally are of no avail. Of course, gouty eczema must be suitably treated.

The great desideratum is the external treatment. I have been in the habit of prescribing an ointment which in most cases pretty nigh approaches the character of a specific :—

℞ Bismuth. subnitr..... ʒ iv.
Zinci oxid. ..... ʒ j.
Acid carbolic liq..... ʒ ss.
Vaselin alb. ..... ʒ ij.

Sometimes I vary the prescription into this form :—

℞ Bismuth. subnitr..... ʒ ij.
Zinci oxid..... ʒ ss.
Glycerini (Price's) .... ʒ iss.
Acid carbolic liq. ..... ♏ xx.
Vaselin alb. ..... ʒ vj.

The latter ointment mixes into a beautiful enamel-like cream which is cooling, and acts as a balm to the irritable skin.

When constant tingling and irritation disturb the patient's rest, I have found the following lotion invaluable :—

℞ Bismuth. subnitr..... ʒ i.
Acid carbolic liq..... ♏ xij.
Glycerini (Price's) .. ʒ iv.
Aq. rosæ .....ad ʒ j.
Shake up and apply with a camel's hair brush.

During the day when business has to be attended to, and the ointment cannot be applied, I prescribe this powder to be dusted on and gently rubbed over the parts affected.

℞ Cimolite
Bismuth. subnitr.
Zinci oxid. āā equal parts, mix.

In more chronic cases the famous unguentum metallarum still holds its ground. It consists of

℞ Ung. zinci.
,, plumbi. acet.
,, hydrarg. nit. āā partes æquales, misce.

This excellent ointment I occasionally vary by substituting white precipitate for the nitrate of mercury ointment.

THE VENTILATION OF PUBLIC BUILDINGS.

By ALFRED J. H CRESPI.

WHAT object ought the designers of public halls, in which meetings are to be held, always to keep before them? Oh, of course, to fit them for public gatherings: what other possible end could they have? That is the very question I should like to have satisfactorily answered: It took me a long time to find out. Anyone who has presided over, or addressed as many public meetings as I have, must have put this question to himself over and over again. Sometimes, as I have noticed people being jammed into remote corners and recesses, where they could neither hear nor see, it has occurred to me that the builders wanted to teach patience; at other times I have fancied that they wished to give people a foretaste of purgatory by packing them on narrow benches, with nothing to support their backs, and without room to stretch their legs. At last I decided to observe the effect upon myself of spending, as one of the audience, three or four evenings a week at public meetings, and then it flashed upon me that the builders of halls and assembly rooms were the best friends the medical profession had in the world. Their object became clear—it was to make people ill, and to find abundant employment for doctors, and it seldom happens that persons are so eminently successful in accomplishing any design which they take up.

A friendly critic in the *Morning Advertiser*, lately spoke with much candour, of some articles of mine as not at all brilliant, and he stigmatised the intense detestation and horror of debt I expressed as neither striking nor original, although, had he been as much hampered with debts as I have been, he would have wondered that I did not use still stronger language. Perhaps, were he to see this paper, he would consider me even duller than he gave me credit for. Why, the very first time I entered a Guildhall, especially if it chanced to be the unventilated little room, which in ancient towns like Bath and Worcester, goes by that time honoured name, I, a medical man, ought to have divined the builder's object, and should have gone away rejoicing. But, positively, it never occurred to me, until my own health was breaking up, that public halls were built and meetings got up in the interests of my professional brethren, and that, as doctors do not take fees from one another, it was, to say the least, unkind to make myself ill and to give unnecessary trouble to a generous friend.

The arrangements of many public rooms are simply disgraceful. It is worse than folly—it is wicked to build halls so low, ill-ventilated, and uncomfortable that the health of everyone who attends meetings in them suffers, and enjoyment and instruction are out of the question. In some towns the only assembly room is a long, low narrow gallery—no other words will describe it—with small windows in one of the two longer sides. No ventilation through the ceiling is attempted, while from the roof hang several large chandeliers, which a tall man, in moving about, finds it difficult not to break. If the windows are opened everyone complains, and very naturally, of the terrible draught; and, much as I revel in fresh air, I cannot deny the justice of their objections. What is to be done? Unventilated, the room is on all, except the coldest nights, a purgatory, and if attempts are made to ventilate it, there is next day an abundant harvest of bad colds, toothache, and tic-doloureux to find employment for several professors of the healing art for three months at least.

On an intensely hot evening, one September, I was at the Worcester Guildhall, a room in which a hundred people could comfortably dine, but which, from the faults I have mentioned, is unfit for a crowded meeting. It was packed to overflowing, and at the back people were standing as close together as human beings could possibly be wedged. Fortunately I was near one of the low windows, and was rejoicing that, if another Black Hole of Calcutta affair happened, there would be some chance of my escaping, but alas, how transient is human happiness! A lady behind me, before the lecture commenced, exclaimed sharply "oh, dear, what a draught. One of the windows is open." Her husband seized the rope connected with the upper sash, or whatever it was that was open, and shut it with a bang. The lecturer, Canon, now Bishop Alfred Barry, whose eloquence, perfect mastery of his subject, and accurate learning could alone, under such circumstances, have kept the audience together, suffered greatly from the

heat. In closing his long and brilliant address, there was deep feeling and much good humour in the manner in which he thanked his listeners for the patience and attention they had given him "in a somewhat painful atmosphere." Now, I ask, why cannot public rooms be made lofty and wide enough to fit them for meetings? Even in the Worcester Guildhall it ought to be possible to attend a meeting, on a warm summer night, without the risk of an attack of typhus.

A couple of days before listening to Dr. Barry, I spoke in a fine, large hall in Birmingham, that had, at considerable expense, been recently beautifully painted. The audience was large, and the closeness overpowering. The room is lighted from the top, and is said to be ventilated through the roof, though no one whom I have ever spoken to appears to have seen the ventilators. I have spoken twenty times at least in that room, and at all seasons of the year, and there has always been the same insufferable foulness of atmosphere. Four or five crowded meetings are held in it every week, but it would be easy to contend that, even in the coldest weather, the heat and closeness are distressing.

A large room in Birmingham, in which I have sometimes spoken, is frequently used for Sunday Services, and for at least two crowded meetings every week. This room, though large, is extremely low. In the windows, at the lower part, is a movable pane, the only means of ventilation. One warm evening, when I happened to be taking part in a meeting there, I ordered some of the nearest windows to be opened, as everyone was oppressed by the heat and foul air. The movable pane was opened, but though only about four feet from the ground, it is so arranged that, instead of directing the current of fresh air towards the ceiling, only twelve feet from the floor—and this would make the draught less destressing—it throws the current towards the floor, and of course, full in the faces of the people sitting close to it. The room is at night lighted by numerous gas brackets fixed within a few feet of the floor, and so, when the movable panes were tilted up on the night in question, a strong draught blew right into the faces of the audience, while the gas began to roar. Of course the windows had to be immediately closed, and when the meeting came to an end no one was sorry. That room, by the way, has only recently been built. After all it is not so much the actual temperature of public halls that is objectionable, though a thermometer has been seen to mark 77° in a crowded room, as the foulness of the atmosphere. One could bear the heat in the open air, but in a closed room, horrible!! A friend was telling me that he thoroughly enjoyed sitting in the open air one day with the thermometer at 82°, but when he entered an unventilated room four degrees cooler, he found the difficulty of breathing most painful and he was soon in a profuse perspiration.

From more than a limited knowledge of public meetings, I am sure that the langour and indifference often displayed are incomparably greater when the room is badly ventilated. A thoroughly attentive and interested audience can hardly be looked for unless the air is cool and fresh, and that can not be counted upon except in the town hall of a great city like Birmingham or Manchester, and not always there.

No doubt it is very philanthropic of builders to think so much of the doctor's interests, but as it is an axiom of this benevolent generation that the happiness of the many should go before that of the few, it would be better to consider the audience rather than their medical attendants. Any person who, like myself, understands the value and comfort of fresh air, would feel the heat and closeness more than most people. Very likely too, as I nearly always have my windows open, day and night, I should complain of the atmosphere of rooms, that would seem reasonably pure to persons who dread fresh air as the greatest of nuisances. By the way have any of my readers noticed that travellers, who have had to camp out for months, often describe the difficulty they find in sleeping in a room unless all the windows were wide open. That shows how sensitive to atmospheric impurities a perfectly healthy human being naturally is. In close rooms health must suffer, although the defective ventilation may not annoy the people sitting in them. It would be out of place here to insist on the importance of efficient ventilation, and on the necessity of good, large, lofty rooms; everybody knows that. But why, in the name of common sense, will people not use their knowledge? Surely everyone is aware that public buildings ought to be so constructed that the height should be as great as the width, and that even for acoustic purposes, the width should not be less than half the length. There should be large windows in both the longer sides, and when ventilation is carried out by movable panes, they should be at the top, not at the bottom of the window, so that the current should be directed towards the ceiling, not into the faces of the audience. Yesterday evening I went into a Church, which has recently been restored at great expense, and the ventilating panes were low down in the windows. Except in calm, hot weather, they could seldom be opened, and there would probably always be a draught. Why, especially in churches, should not numerous ventilating apertures be made in the upper part of the walls, not merely six small holes as one often sees, but, when the building is large, sixty or eighty. And these apertures ought never to be closed. It is seldom agreeable to sit a long service out in the gallery of a church or chapel, the ventilation is so bad, and the heat so oppressive. On many occasions, when the closeness was overpowering, I have been assured that all the ventilators were open.

Suppose we try to imagine,—and a very strong imagination is needed, that the builders and designers of new churches and halls wish to make the audience comfortable, one would expect few difficulties. The want of money is the principal complaint and is made the excuse for every fault of omission and commission. The saving by doing without architectural ornamentation would, in many cases, enable the walls to be carried a few feet higher, and health ought always to take precedence of architecture, although when the funds will admit of it, it not only ought, but should, have its full share of attention. Again, why is it necessary to build public rooms in crowded thoroughfares, where land is fabulously dear? The saving by putting new churches and halls in side streets would often in great towns, make all the difference between a badly-constructed, ill-ventilated room, and one which would answer all the ends, that in such circumstances should never be forgotten.

A public building generally lasts many years; it is ostensibly built for holding meetings, and should be adapted to this end. When sufficient funds are not forthcoming to cover the expense of large, permanent, well-ventilated rooms, it would show greater wisdom and foresight to put up temporary iron structures, which would answer well enough for a few years, and in due time it might be possible to replace them with scientifically constructed, durable places, in which it would be a pleasure to pass a few hours occasionally.

In proportion to its cubical space, more persons can be comfortably placed in a large than in a small, low room. Dr. Parkes thought that in this climate it would be impracticable, without giving rise to unpleasant draughts, to change the air of a room oftener than three or four times an hour. Obviously, then, to prevent the air from getting offensive and injurious, sufficient space is indispensable. But a small crowded room, cannot, whatever is done, be properly ventilated, nor could the air be changed four times an hour, because it would be impossible to arrange the ventilating apertures so that strong draughts would not arise. The greater the difference between the temperature in the room and that of the air outside, the more violent would be the draught, so that there would be an almost irresistible temptation to close every inlet, however small. Moreover, the atmosphere of any room, will have its temperature still more rapidly and painfully raised if many gas burners are alight, and if the air exhaled from many lungs is being discharged into it. Perhaps it is particularly fortunate that when the room is so much hotter than outside, do what people like, they cannot keep out a good deal of fresh air, and currents rapidly pass through the walls and the floors, while through every chink and hole the current is continuous.

Surely if the interests of the listeners go for little, those of the speakers ought to be considered. It is most trying to speak for an hour and a half, when your head is aching violently and you are half suffocated. And how can you expect the grandest flight of rhetoric to have its due effect on your audience; how can you hope that the reporters will understand you? Not long ago I chanced to be in the Bath Guildhall, and considering the atmosphere, it was as well for my relatives that I had previously taken the precaution to insure my life heavily. The speaker was Canon Basil Wilberforce, of Southampton, and the subject was Teetotalism. I regret to add that the unqualified assertions and boundless promises of that ardent young clergyman failed to impress his listeners as they ought. But what could he expect in a room the atmosphere of which was little worse—better I mean—than that of the Grotto del Cane, near Naples? With charming good nature, and apparently perfect faith, "Dean" Wilberforce, as the teetotalers used to designate him, before they styled him *The Canon*, spelt with capital letters of the largest size, or, as he was called by a medical man at the Bath Meeting, the "Dean of Southampton," promised the chairman—a venerable admiral, near the end of his travels, judging from his appearance—ten additional years of life, if he would forthwith sign the pledge and become a total abstainer. It was no use. The mephitic atmosphere made it impossible for the admiral to understand the promise, much less to act upon it; nor would he agree to give a £10 cheque to the temperance society which Mr. Wilberforce represented, though earnestly pressed to do so. What wonder that chairman and listeners should be wool-gathering, even when the ardour of the speaker led him to make such wonderful promises as ten additional years to a man not apparently likely to live five! How many years extra would Mr. Wilberforce promise a young man, if he would become a total abstainer? Fifty, at least. But in the poisonous atmosphere of the Bath Guildhall, on a warm spring night, few converts, young or old, could be made.

No, in the interests of speakers, chairmen, and listeners, we must have better and larger public rooms; and when we have got them, care must be taken to ventilate them properly and scientifically, and in new rooms and churches there should be no false economy.

In public buildings, not used for meetings, it is equally important to remember that, unless there is ample space, efficient ventilation is impossible. Rooms in which people are to live and sleep should be large enough to make it easy to change the atmosphere three or four times an hour without inconvenience. And ventilation will be easier and more thorough if the house is not greatly hemmed in at back and front, and if every reasonable facility is afforded for the free circulation of the air in the house itself. Ventilators should be fixed in all walls and over all doors. The result could not but be beneficial, and in the long run, perfect ventilation might actually give every man on the average some additional years of life.

The following remarks are neither very striking nor original; though their truth everyone must admit, and there the matter will end; it is really too preposterous to expect that anyone will try to practise what everyone knows, for how many show their faith by their works? Granting that it is decided not to allow the air of a room to contain more than six feet of carbonic acid per ten thousand; admitting, too, that a healthy adult man gives off fifteen cubic feet of carbonic acid in twenty-four hours; and assuming that every ten thousand feet of ordinary fresh air contain four feet of carbonic acid, an adult would require nearly seventy-five thousand feet of fresh air a day, or, supposing that he were confined to a room containing a thousand cubic feet, the air would need to be changed three times an hour, day and night. Were the air changed five times an hour, the space per head need not exceed six hundred cubic feet. Were it thought that air could be safely breathed, containing as much as seven feet of carbonic acid in ten thousand, the space per head could be reduced, and might be four hundred only. In the better class of houses this allowance of air and this dwelling space are commonly provided, and, therefore, as far as their occupants go, there is generally little cause for complaint. In the poorer sort of houses the supply is much smaller, and the accommodation more restricted. But in practice it is not found that the atmosphere, even of good sized rooms, is sufficiently pure and agreeable to satisfy the sanitarian, and the explanation is that allowance is not made for the impurities which large fires, stoves, candles, and gas burners give off. An ordinary gas burner requires, on an average, the oxygen of twenty-four cubic feet of air, and gives off, in addition to other impurities, six cubic feet of carbonic acid per hour. In other words, one burner produces enough carbonic acid to make thirty thousand feet of air of average purity injurious. Two burners will, in an hour, consume as much air as would support a healthy man twenty-four hours. The supply of fresh air for the human inhabitants of a house is not therefore the most important matter, every burner needing a supply equivalent to that of eleven or twelve adult men. Then there are other animals, as large dogs and cats, that do their best to consume the oxygen in the generally inadequate supply of fresh air; and, last, in the better class of houses, not less than in respectable cottages, plants are often allowed to remain in sitting rooms all night, absorbing oxygen, and giving off carbonic acid. What wonder that in most houses, unless the windows are kept open, and the arrangements for ventilation are perfect, the air is stuffy and impure, while, as for public halls, where there may be no pretence at ventilation, and where, in a confined and insufficient space, a thousand people

and a hundred burners may be heating and poisoning the air, what can be expected.

The thorough and constant ventilation of houses is a matter of primary importance. Impure air cannot be breathed with impunity, month after month, and year after year. It is bad economy to inhabit small, ill-ventilated rooms, because they are lower rented than larger ones. Perhaps foul air is an evil not inferior to intemperance, and in the aggregate probably causes greater mischief, and directly or indirectly affects more people.

Oblong rooms are not so well adapted for sound as oval ones, and it is much better to arrange the seats so that the audience should face the platform and the speaker. In Town there are several important chapels, notably, Mr. Spurgeon's Tabernacle, and the vast one near the Wellington Barracks, in which the interests of the audience and the speakers, rather than those of the doctors, have been considered. The success has been signal, and even people sitting in the galleries can see and hear. Thorough ventilation, the avoidance of sharp corners, and a certain elevation, are the great thing, and so the objections to, and discomforts of most crowded meetings might, in some measure, be neutralised.

As soon as the habit is formed of living in large, well-ventilated rooms, it is exceedingly painful to pass an evening in a hot, impure atmosphere. And what a gain too there is in other respects in getting to love fresh air and learning to live in it: you enjoy life more, need smaller fires, are able to get through more work, and live longer. Were public halls well ventilated, who knows, even dull speakers might become lively; and those would-be orators who repeat the latter half of every sentence, having forgotten where they left off, might, in a clearer atmosphere, talk more coherently and intelligently, and weary their much-tried audience less.

ON THE APPLICATION OF ANÆSTHETICS IN NATURAL LABOUR.[1]

By M. Charpentier, M.D., Paris,

At the time of the publication of my "Treatise on Confinements" in 1883, I devoted a long chapter to the application of anæsthetic agents in natural labour. It seemed at this epoch interesting to group the documents relating to a question so much the subject of controversy. I then gave a detailed history up to 1878—the epoch when Pinard, in his *thèse d'agrégation*, concluded that anæsthetics should be rejected. Numerous papers have been since published, such as those of Dutertre in 1882; Hofmeir, Sawill, Morris, 1883; Muller, 1884; Cohn, 1886, etc. The most complete is that of Dutertre, who—in opposition to Pinard—declares himself a resolute partisan of the employment of chloroform in natural labour. Here it is necessary to make a distinction: sometimes anæsthesthia is given up to complete narcosis; this is *surgical anæsthesia*, and all accoucheurs are in agreement upon it. They reserve it for cases when obstetrical intervention is demanded, in the interest of the mother or the infant—forceps, version, embryotomy, etc. Sometimes, on the contrary, anæsthesia need not be pushed to complete narcosis. Here we have to deal with what is known at the present day as obstetrical anæsthesia, and this is the form I wish to speak about on the present occasion. Employed regularly abroad, obstetrical anæsthesia even in France now meets with, in reality, little opposition, and almost all accoucheurs recognise its advantages and its innocuity, if not in every case, at least in a good number of circumstances, which I shall pass in review under the heading of indications. Obstetrical anæsthesia comprises two great varieties.

1. General anæsthesia.
2. Local anæsthesia.

I.—*General anæsthesia.*

There are three principal agents—viz., ether, chloral, chloroform, and a series of mixed agents composed of various combinations. There are two other agents—though of very limited use—bromide of ethyl and protoxide of azote.

1. Ether, employed for the first time by Simpson on the 19th of June, 1847, vigorously attacked by Montgomery, Barnes, Gream, Reid, Ramsbotham in London, and Meigs (Philadelphia), accepted on the other hand by most of the other learned societies of the United Kingdom, is still employed by most physicians. In France it had little success, and was promptly replaced by chloroform, which is to-day the current anæsthetic agent.

2. Chloral, which we employ in the usual manner, not—properly speaking—as an anæsthetic agent, but as a powerful calmative, which allows us to procure for the parturient artificial rest at any moment of labour. It is in effect impossible to keep women under the influence of ether or chloroform from the commencement of labour to the expulsion of the fœtus. Now during the first period, that is to say, that of dilatation, a time so painful, and so badly borne in general by patients, chloral has an indisputable efficacy, employed in lavements: dose—three to four grammes, and renewed at need every three, four, or five hours. It is especially useful in cases where the back pains are very painful. Where dilatation proceeds slowly, either on account of weakness of the contractions, their irregularity, or on account of rigidity of the os in primiparæ, chloral should be especially employed. Not only has chloral no injurious influence on uterine contraction, but often it regulates it, leaving to it all its intensity; it thus notably diminishes the duration of labour. In the last half of labour chloral has a much less decisive action, and we must resort to chloroform, or local anæsthetics, if we want to give our patients real relief.

3. Chloroform was discovered in 1831 by Souberan in France; Liebig in Germany. It was employed for the first time by Simpson in 1847, and it first met with the same opposition as ether, but the two confinements of the Queen in 1853 and 1857 soon put it *à la mode* in England. Chloroform *à la reine* become of current application in the hands of Merriman, Murphy, Gream, Stallard, Lansdown, Protheroe, Smith, Denham, etc. The employment of chloroform in obstetrics spread from England to America. In spite of the efforts of Meigs (Philadelphia), Channing and all the accoucheurs employed it regularly in natural labour. In Germany, Siebold, Sachs, Scanzoni rejected it. It is, on the contrary, recommended by Breit, Krieger, Orlowsky, Kiehl, Grenser, Haller, Kiwisch, Harnier, Winckel, Spiegelberg, Schroeder, Martin, Hofmeir, etc. In Russia, Pirogoff, Mianowsky, Kurowicz, Tarnowsky, Hugenberger, and Krassowsky employed it in natural labour. Levy at Copenhagen; Howitz, Heyerdahl, Schidlart in Scandinavia; Romiti, Corradi in Italy; Piachaud in Switzerland; Hubert, Hyernaux, Charles in Belgium are partisans of anæsthetics. In France anæsthesia had more difficulty in spreading, in spite of the observations of Fournier Deschamps, 24th June, 1847; the experiences of

[1] A paper read at Obstetrical and Gynæcological Society, Paris, May 22nd, 1889, and published in the Bulletins of the Society.

Paul Dubois; the works of Houzelot, Blot, Bouchacourt, Courty, Bailly, Legroux, Dumontpellier, and especially of Campbell. Anæsthesia applied to natural labour is combated by De Paul, Pajot, Pinard; accepted with certain reserves by Barquissau, Chailly, and praised anew by Dutertre, Lucas-Championniere, and Budin.

Practitioners who have used chloroform know very well that between the first period—excitation, and the terminal one—narcosis, there exists an intermediacy period, characterised by a kind of chloroformic ebriety, which notably weakens the intensity of perception, by obnumbration of the nervous centres; and that this ebriety is compatible with the persistence of reflex sensibility. Now this is precisely the aim of obstetrical anæsthesia; it seeks to bring about a state of relative insensibility, to suppress excitation without reaching narcosis. The condition indispensable and difficult to realise in practice is, to know how to regulate and moderate the action of the anæsthetic. Those who observe without prejudice feel no doubt that if chloroformisation be long continued, when the dose of chloroform is augmented to totally suppress the pain felt by the women, or even, on the contrary, if moderate doses are given, we arrive more or less rapidly at, or pass, the state of chloroformic ebriety, and produce true narcosis. The proof of this is furnished by the slowing and weakness of the contractions; then by their almost definite cessation. If the chloroformisation be prolonged, obstetrical anæsthesia constitutes then less a scientific unknown quantity than a practical difficulty, which may vary with each new application, and with each individuality—hence the numerous and discordant discussions of different authors. Now if we took the works of men who have studied the question with the greatest care, without wishing to enter on the intimate mode of action of chloroform on the nervous system, we shall see how its action is explained. Spiegelberg has established:

1. That if we give chloroform progressively mixed with air, sensibility diminishes, and, in particular, pain of contraction; that intellectual consciousness is preserved, that the woman feels herself relieved, and that the uterine contractions at first weakened, soon return more frequently and more regularly. As Beally and Bailly say, the women know that they have contractions, but they do not feel them. In suspending and alternating the inhalations, women can be maintained for a long time in this condition, which constitutes the first stage—obstetrical anæsthesia.

2. That if we continue the inhalations without interrupting them, the second stage is reached, that of complete narcosis. Consciousness and mobility are lost; reflex action being weakened, the uterine contractions become slower, but they preserve their force; the same being true of contraction of the abdominal muscles.

3. That if we push the chloroform further, the third stage is reached: there is stupor, coma; uterine contraction becomes feeble and rare.

Resumé.—In the first stage there is no influence on contraction. In the second stage, if we give chloroform in the onset in large doses, there is initial weakness of the contractions; then a return to the normal state. In the third stage there is diminution of contraction; complete cessation may be maintained by pushing the chloroform. But then the woman runs serious danger, for the heart and other muscular viscera are paralysed as well as the uterus. The infant is not influenced by the chloroform.

(*To be continued.*)

CHILL, OR RIGOR.

By WILLIAM H. PEARSE, M.D. EDIN.,

SENIOR PHYSICIAN PLYMOUTH PUBLIC DISPENSARY.

1. *Its Frequency.*—Rigor is found associated with a great number of the deviations from health to which the body is subject—*i.e.*, it is a change common to a great number of what our nomenclatures call "different diseases." These different diseases include the great Fever group—the exanthemata, the acute inflammations, the febro-inflammations, such as the border-land febro-infective pneumonias, epidemic febro-bronchial cases, infective dysentery, acute syphilitic fever, cynanche, herpes, etc. Rigor is perhaps the most general fact in pathology. It may fairly be viewed, in point of frequency, as an approximative basis of pathology. We may also justly think that it is a basis in comparative pathology. We see our pet birds die, within a day or two after a persistent ruffling of their feathers, and by analogy we may fairly surmise that this condition is associated with rigor. Other animals exhibit the same phenomenon, and with fatal results. As far as ordinary observation goes, we may ask, Under what conditions does rigor arise?

(*a*) With and after emotions of fear, joy, etc.

(*b*) With and after changed modes of nerve and other tissue—*e.g.*, as in passing a catheter, syringing the ear, micturating, etc.

(*c*) After taking food and drink.

(*d*) With and after externally-changed environment.

We count up such external conditions and call them "causes," but they are, each and all, but facts in an orderly continuity. Take, *e.g.*, the seemingly-simplest of these external conditions which is followed by rigor or chill—that of taking food or a drink of water. Every cell-contents in the body is changed in its modes and correlations by the mere absorption of water from the stomach. Or take the example of a mere change of place or shift of wind. Every molecule of protoplasm within the body must have its equipoise of correlation disturbed and changed by both change of place and shift of wind. If to some minds such views are not *à priori* evident, and are not seen as necessary truths, flowing from the conditions of the cosmic evolution of the organic, they have at least been abundantly demonstrated by experience, for at recurrent periods cholera, yellow fever, etc., have evolved, or their conditions been precipitated, by changes of drinking water, by changes of place, changes of wind and weather, etc. It seems just to hold that the Form or modes of rigor are present when the extreme sense of rigor may not be so manifest—*e.g.*, severe rigor often ushers in small-pox and yellow fever, but the amount of sensible rigor varies greatly in degree. Men are stricken down with black-vomit at once, with hardly-recognizable rigor. The worse-type cases of small-pox—the hæmorrhagic—often show with hardly any of the course of symptoms which are characteristic of typical severe small-pox. The rigor which ushers in a case of herpes or cynanche tonsillaris is often far more severe than that which precedes a fatal case of hæmorrhagic small-pox or yellow fever. But although rigor in some cases is so little manifested, yet it is the widest yet-recognized change, in common, to the great fever and febro-inflammatory groups. Even if it be seemingly absent in certain cases of yellow fever, cholera, etc., yet analogy compels us to see that its essential Form and process has, not the less, been existent.

We have then in rigor a so-far ultimate basis in patho-

logy. Our conception of the orderly methods of nature compels us to see that a great unity of process pervades the Form of so many of our "different diseases." It is important to bear in mind that rigor is but a *so-far* basis in pathology; because prior to its occurrence there must have been reached an unstable vito-chemical mode of protoplasm and albuminoids—without which, the changed place, or water, or wind, or emotion, or shock, could not have brought about the molecular vito-chemical disturbances which rigor reveals. It would be strange indeed if the highest and most differentiated, and most cosmically correlated, and complex, of all evolutions—the organic—should not be found to be as rigorously and absolutely under law and order as are the more elementary, mechanical, physical, and chemical motions and affinities. It seems therefore just that we should dwell on rigor as a fundamental fact in pathology, both when viewed by the general analogies of philosophical method, and by the observations of its great frequency in disease.

2. *Its Primary or Early Occurrence.*—We have seen the vast range over which rigor occurs; we equally see that it expresses the earliest changes in protoplasm from the rates, composition, and modes of health.

It seems as an *à priori* truth that the changes involved in, or productive of, rigor are in continuity of law with normal rates, or health. Like to the changes, say in nitro-glycerine on the addition of rapid motion or heat—percussion—there is nothing added to albumenoids, nothing lost; but there is disturbance of molecular bonds and changed intermolecular motions and modes of motion. New bodies are formed, or new and inharmonious motions and correlations are established. We are sure that the intermolecular vito-chemical changes which rigor reveals must be as orderly and by law as are the changes in all other chemistry. We further see that in the almost universality and primary occurrence of rigor, that it implies a universal Form and generic orderly law. Although the "diseases" which follow rigor are, in our present state of knowledge, justly enough grouped as "different," yet observation and analogy point to their greater unity. We can no longer regard the realms of nature either in 'elementary' (?) matter, compounds of matter, or in species or genera; or in the different parts of the living animal; or in races and languages, institutions, or philosophies, as mapped out, with "specific" differences: nor can we regard the best demarked fevers as specifically different; they have all a great generic unity of method and course primary rigor, followed by pyrexia. But albumen is not one simple body, but "compounded of many albumens, having *very nearly* the same composition. . . ." (Schutzenberger). In view of the high atomic constitution of albumen, and in view of the so-different environment as is involved in different latitudes, the devolutions or vito-chemical reversions of albuminoids and protoplasm must necessarily be varied, and thus the fevers of one latitude and place vary from those of another latitude; but their great type is one and the same: the primary rigor has always the same generic type of change whether it be followed by herpes and pyrexia in England, or by black-vomit and pyrexia in Vera Cruz. It appears to me that it is to forsake all philosophical analogy unless we look for one grand type of vito-chemical reversion as the basis of the great fever and febro-inflammatory groups, and this reversion is revealed by Rigor. Rigor is made conscious to us—in the recognition by the fundamental energy and "irritability," and their higher differentiations in and of us, of primary vito-chemical changes in the modes and molecular motions and correlations of protoplasm. It reveals death, more or less, or reversion of highly-differentiated chemical bodies to more stable bodies, with consequent evolution of heat.

3. *Approximate Groups of Diseases which have Rigor as a Fundamental Stage.*—The history of knowledge has often shown that our greatest advances in method and generalisation have been by following some apparently simple facts. In medicine, the most harmless phenomena of disease must be in continuity, or of the same class or Form as those greater disturbances which are so fatal to life. I would, therefore, refer to those classes of cases seemingly simple, but pathologically profound, which are expressed by patients, by such words as "chilliness;" by chilliness followed by a general "soreness of bones," "soreness of body," "aching all over, as if I had been beaten," etc. These symptoms are often associated with pyrexia and headache. No localisations of disease can be discovered, and it is impossible to say whether or not such symptoms are the early stages of a continued fever. A careful observer will, however, seldom be in error of judgment, as they are generally in our latitudes more sudden and acute than is the onset of a continued fever. But is it possible to doubt that their method and pathology are absolutely generic with those of more serious fevers? Such cases appear to be revealers of the method of nature. The physcist or chemist does not seek to unravel the universal laws of nature by observation of the greatest phenomena of those laws. They study the most simple examples, and, finding their order and laws, apply such laws to the largest and most complex phenomena. On the same principles of method the simpler classes of diseases which I have cited may become revealers of the widest laws and Forms of pathology.

From the equator to high north and south latitudes man shows fevers. Somewhat constant types of such fevers belong to certain latitudes, but such a law is far from absolute—*e.g.*, yellow fever, which is an endemic tendency of Europeans in the Gulf of Mexico, has, now and then, shown in the Mediterranean and English latitudes; typhoid, endemic to man in from 40° to 60° north latitude, has evolved out of protoplasm in India, South Africa, and in the virgin forests of New Zealand, etc. Indeed, there have been ever appearing, fevers, which, observers being unable to group under orthodox names, have received new names, generally taken from the localities of their occurrence—*e.g.*, we have had Wallachern fever, Cape-coast Castle fever, Nuddea (Sunderbund) fever, etc. Thus there exists a vast range, and a vast but graduated and related series, of fevers. But more than this, during epidemics of yellow fever, cholera, etc., many "other diseases" tend to assume the aspects of the greater types. In a descriptive sense we are compelled to give names to our diseases, but we must with constant care remember that the whole of the varied groups and different diseases have a profounder unity and pathological continuity. The most general and primary symptom of the vast and varied, yet allied series—the fevers from 0° to 70° north and to 50° south latitude—is rigor. All the analogies of the simplicity of nature compel us to feel that the fevers we call agues—quotidian, tertian, and quartian—well demarked as they often are, are but gradations of one series. Indeed, what was at first a quotidian will, after a time, become a tertian or quartian. In the natives of India "fever" assumes the most graduated series. They are subject to

fever, which they call *tap* and *bukhár*, which cannot be justly classed under either of the intermittents, and which will appear in them after a great variety of shocks or exposures or depressions. Further, natives will exhibit fever, which one is obliged to call remittent, but of most varying degree and duration. Rigor is the phenomenon common to the earliest recognizable stages of all these types—rigor, with the subsequent pyrexia.

But if rigor is a basis of the great fever group, it is no less so of what we call the true inflammations. We all recognise the differences between a case of typical pneumonia in a young and seemingly healthy farmer, and a case of continued fever; but, on the other hand, we have infective pneumonia, epidemic pneumonia, and cases where the degree of pneumonia is slight, but the general fever well marked. In fact, fever and pneumonia are often, according to just and common observation, far more allied than distinct, and rigor is a so-far primary base of them all. One of my most serious impressions of comparative disease was that of an epidemic of bronchial fever, amongst young adults, in a voyage from Birkenhead to Melbourne in 1857. In the earliest weeks many had small, moist, catarrhal râles at the bases of the lungs, without dulness on percussion, and associated with rigors and malaise. As the voyage progressed, the cases assumed a fatal fever type. Many died. I have seen bronchial fever in other voyages. In fact, the word "bronchitis," as expressing in the main a disease within the lungs, not only circumscribes our view, but is misleading in pathology. Bronchitis, in many cases, is more a fever than an inflammation; it is truly a general disease. If one may dare to build any inference on the quicksands of treatment—though one would never neglect the aim of the fit use of strychnine, belladonna, strammonium, opium, etc., in reference to spasm—yet I have often given quinine and a mineral acid with as much satisfaction as has been given in other cases by the orthodox stimulo-expectorant mixtures. I hope that I have now cited enough of the great fever, inflammatory, febro-inflammatory, and border-land groups, to illustrate the phenomena of rigor, as in a great degree a basis common to them all; and to illustrate further, that gradation and alliance have a greater place in the form of these diseases than have their differences. The doctrine of the "specific" seems to subside.

(*To be continued.*)

Special Articles.

HEALTH RESORTS OF THE WORLD.

XXXIII.—BATH.

BATH is one of the oldest and the best known of our health resorts, though it has experienced great changes in its fortunes. Its Pump Room, which received on June 13th the Duchess of Albany and the distinguished guests of the Mayor and Corporation at the installation of the new baths, had seen all the stately dignataries of the generation of Beau Nash, and its floors had been trodden by belles and beaux of fashion of the Regency. But this is modern history in connection with the life of Bath. It has a history interesting to the archæologist. It was one of the Roman stations, and, if we may believe our historians, its origin as a natural health resort may be attributed to the Romans, who called it the "Water of the Sun." The Saxons named it the "City of the Sick." The Roman Thermæ were destroyed A.D. 577, and re-established in the seventh century; enlarged A.D. 1235, 1575, 1664, 1750, 1788, 1859. In 1588 a book was published by William Lampard, called the "Office of the Justice of the Peace," and in it we find the following reference: "Two justices may licence diseased persons (living on almes) to travel to Bath to remedy their griefe." On the site of the temple of Diana we were informed by the Mayor of Bath in his address to the Duchess of Albany, June 13th, that the present Pump Room stands, so that the historical traditions of the baths are carried down to our time.

The 13th June was a memorable occasion in the history of these springs. The circumstances attending the ceremony were carried out with a magnificence worthy of a rich and hospitable corporation. From all parts of England medical men were invited, and, in order to lighten the burden of expense to the guests, the Corporation sent them first-class railway passes. A special train left Paddington at 10-30 laden with medical men from the metropolis and the provinces, who, on their arrival, were received with all honour by the Mayor and Corporation. Special carriages were in waiting to drive them to the Guildhall to partake of the civic hospitality in the shape of a magnificent luncheon, and as the visitors drove through the streets of Bath, it was evident that the city was in a holiday mood. The streets were lined with citizens; houses were decorated; arches spanned the streets, and the scene was enlivened by the presence of the local volunteers, who lined the route through which the guests passed to the Guildhall, where a luncheon, given by the Mayor, W. H. Freeman, F.R.C.S., of the choicest character was served.

After the usual toasts of the Queen and the Royal Family, the profession was honoured by a special toast, "the distinguished members of the medical profession." This was appropriately proposed by the Mayor who in the name of the city most heartily thanked the medical men for their presence that day. They had rallied round them in large numbers on that very interesting occasion, many at great personal sacrifice and inconvenience. He coupled with the toast the names of Dr. Peel-Ritchie, President of the Royal College of Physicians, Edinburgh, and Dr. Broadbent, who responded in suitable terms. Great disappointment was manifested at the absence of Princess Louise, who had promised to open the new baths, and universal regret was expressed on account of Her Royal Highness's indisposition, but the readiness and heartiness with which the Duchess of Albany stepped into the breach and took the place of her distinguished relative compensated for any inconvenience that had been caused, and secured for the widow of the Queen's youngest son a most cordial and loyal reception. The Duchess arrived at two o'clock, and was received at the Sydney Gardens siding, by the Mayor, the Mayoress, the Marquis and Marchioness of Bath, the Earl of Cork, and the Bishop of Bath and Wells. Her Royal Highness drove to the Guildhall, and after a brief stay there proceeded to the celebrated Pump Room, where, on behalf of the Princess Louise, she received several addresses and listened to an admirably concise explanatory speech delivered by the Mayor.

The Mayor, addressing the Duchess, said:—Your Royal Highness: In the name of the Corporate body of this ancient city I am greatly pleased at Your Royal Highness's kindliness in coming here, and for your graceful condes-

cension in responding so readily to our prayer. We deeply regret your Royal Highness the indisposition of your august relative, and we trust that she will speedily be restored to health. The room in which your Royal Highness now sits is the Grand Pump Room; it was built in the year 1796. Two thousand years ago on the ground on which we are now standing stood the temple of Diana. On the site of the Abbey Churchyard and the Abbey stood the "Hall of Justice," the basilica. At the west end of the Abbey Churchyard, and to our left, stood the great temple of Minerva, the presiding genius of the water. The great portion of the Churchyard was mainly occupied by a suite of Roman Baths. These hot baths were of very ancient origin. The Romans enclosed the springs nearly 2,000 years ago, and developed a remarkable system of thermæ, the remains of which your Royal Highness will be graciously asked to inspect this afternoon. Since that time there had always been a bathing establishment here. At one period, however, the baths were forgotten, and were most obliterated during the Saxon period, but were rebuilt in the early Norman period. Again they fell into disuse, but three or four centuries afterwards, in the time of Queen Elizabeth, and subsequently, we find them flourishing with various degrees of success. In 1755 the first discoveries of the Roman remains was made, but it is within the past 10 years that excavations have been carried out by our City Architect, Major Davis, who has brought to light the extensive Roman remains of to-day. The baths which you will graciously open were commenced in the year 1886. They have been erected in connection with our Pump Room on the site of the old Queen's Bath and of some of the Roman remains. These new baths are a replica of what we find on the Continent, notably those at Aix-les-Bains; and it is primarily with a view of developing the Aix-les-Bains treatment that the Corporation has ventured to spend the large sum of £25,000 upon this building. Again, your Royal Highness, let me thank you, in the name of our ancient city, for the self-sacrifice you have made in coming amongst us to-day.

Before leaving the raised *daïs* the Mayor handed to the Duchess a handsomely bound volume, containing a series of views of Bath and its environs, and also his new work on "The Thermal Baths of Bath." General Mainwaring (President of the Royal Mineral Water Hospital) handed to H.R.H. a book containing an account of the history of the Institution over which he presides. The book, which was bound in French morocco, contained the following inscription:—"History of the Royal Mineral Water Hospital, Bath; by the late R. W. Falconer, M.D., continued by Anthony Beaufort Brabazon, M.D. Presented to H.R.H. Princess Louise, June 13th, 1889." Major Davis also presented H.R.H. with his work on "The Roman Remains."

From the Pump Room the visitors proceeded through the new bathing establishment, the various methods of applying the waters being explained *en route*. On reaching the Rectangular Roman Bath, a halt was made at a point where a covered awning had been erected, in order to allow Major Davis to explain to the company details of the various discoveries, which he did in a paper which we reproduce.

"Your Royal Highness, my Lords, Ladies, and Gentlemen,—With your permission, and by request of the Mayor, I am permitted the short interval of ten minutes to bring to your notice our ancient baths. In your progress through the new Queen's Baths you doubtless observed the Roman Hypocaust and also the fragments of walls, on which the architect of the new building was compelled to build the new structure of the Queen's Bath. Immediately after leaving the Vapour Bath you crossed the mediaeval King's Bath, so named, either in consequence of its having been originally Crown property, or in remembrance of the numerous Sovereigns who have bathed in our springs. This bath is immediately above the Roman well, discovered by me a few years since, which encloses an area of octagonal form of somewhat the same size as the King's Bath. This well, formed of colossal material by the Romans, was built to secure the water from contamination, and also for the purpose of confining them within a limited area. The mineral water in this well is at present secured by an intermediate floor between it and the King's Bath. A building in the centre of the bath in the form of a drum is the only opening to the spring, over which the water flows, as you have seen it, in volume about 200 gallons a minute, and at a temperature of 116 degrees. This water is distributed by various aqueducts throughout the whole of this establishment, and supplements the other springs of the baths which your Royal Highness has yet to visit. This great Roman wall was the centre of a system of which the bath, on the schola of which you are now sitting, was one of the principal baths. It is always difficult to realise the precise size of a ruin, more especially, as in this case, where the fragments are in such large proportions, but I may compare it with advantage to the banqueting-room in which the Mayor has had the honour of entertaining you. The dimensions of that room are 80ft. by 40ft., but this bath is more than double that size, and when it was complete was as lofty as, if not loftier, than the banqueting-room referred to. I have every reason to believe, from what has been discovered, that this bath is only one of many similar ones, and that the Roman Thermæ in the forth century covered an area exceeding seven acres, and accommodating at one time upwards of 1,000 bathers within its walls, not to mention the much larger area of the gardens and recreation ground that undoubtedly adjoined the baths. It is difficult to assign a precise date to the earliest formation of our baths, as various dimensions I have taken singularly agree with figures that are believed to have been used in south Britain prior to the Roman conquest. Without venturing to ascribe an earlier than a Roman date, it is generally conjectured that they were found by the Emperor Vespasian or his son Titus. We may therefore claim an antiquity of eighteen centuries. The excavations made under my directions have included many discoveries, amongst them this large bath, a large Circular Bath, which your Royal Highness has yet to visit, and several others, all of which had scarcely been anticipated by antiquaries who had studied the subject. In 1734, to the east of this great bath, important Roman work was discovered, but unfortunately destroyed. I am afraid I cannot detain you, or I could explain more in detail the various discoveries, and must therefore be content to mention that this great bath is a type of the others. The water surface of the bath is in the centre of the Hall and enclosed by steps, around which is the schola or platform. The blocks of pillars dividing the schola from the bath are the fragments of a colonnade with arches between, that supported three vaults, two over the scholas and a larger vault in the centre spanning the bath. Fragments of this central vault, as they fell on the destruction of the Baths, are beneath the water. Light was admitted by windows, the arch of one, as it fell, is still at the west end of the bath. These Roman Baths were altered and enlarged at

various times, and on the Romans leaving Britain they were still enjoyed, although the buildings were not maintained in their original extent or in perfect repair. In A.D. 577 Bath was taken, and destroyed by the Saxons, and the place became a waste, and wild fowl laid their eggs in the rushes that grew on the margins of the springs. The heat of the waters was ascribed to magic, and the valley was forsaken. St. David blessed the springs, and King Arthur, we are told, was present at the ceremony; the evil spirit was banished, and the waters, as in the past, were health-giving and the cure of every sickness. A city sprang up under King Offa in the eighth century, and 973 King Edgar was crowned in Bath; and we will hope that the ceremony was not complete without a bath in our mineral waters, although the baths were then confined to the simple area of the springs. This, and the Cross Baths, which was also placed immediately over the springs, sufficed, together with the Leper's Bath, for bathing until the middle of the century. It was frequently suggested that the baths should be covered, but that expense was never incurred. Many of our Royal Sovereigns, including Queen Elizabeth and succeeding Kings and Queens, bathed in the King's Bath. In 1618 the Queen of James I. preferring a smaller bath adjoining, it was named after her, and it was only recently removed to make way for the new buildings, disclosing the large Circular Bath, which has still to be visited. Among other donors, Sir Francis Stonor, the ancestor of Lord Camoys, presented as a thank-offering a handsome balustrade in 1618 that still in part surrounds the King's Bath. In 1664 a building, as a partial covering for the bathers, was erected in the centre, taking the place of an ancient stone cross. A drawing made in 1665 exists in the British Museum showing a crowd of bathers in the bath, with the surrounding galleries full of spectators. As I am instructed to speak more particularly of our ancient baths, I refrain from approaching more modern times, except to express the hope that your Royal Highness approves the structure and arrangements of the new Queen's Bath, which I, as the architect with undivided responsibility, have laboured with considerable thought and anxiety to make the most perfect bathing establishment in Europe, and to effect this result as far as possible under the circumstances, without sacrificing any fragment of the ancient baths—to reconcile, in facts, the exacting demands of modern utility and medical science with a scrupulous regard for historical and antiquarian interests, Within a limited area every appliance of administering water and vapour will be found that is afforded elsewhere, together with several entirely new. Altogether forty different means of treatment can be prescribed in the new Queen's Bath with every comfort and convenience. The Queen's Bath was originally named after Queen Anne, but to make it doubly the Queen's Bath, a bust of her present Majesty has been place on the exterior to commemorate the Jubilee of Queen Victoria." The Duchess of Albany and visitors inspected the new bathing establishment. Each visitor was supplied with a printed guide, showing the number and nature of the different appliances for the benefit of patients. We personally inspected the baths, and we are able to speak in the highest terms of their excellence. They are complete in every respect, and few continental spas can vie with them.

THE NEW BATHS.

We are indebted to the *Bath Argus* for the following very full account of the new establishment.

THE UPPER FLOOR.

To everyone has not been given the opportunity of inspecting the new bathing establishment, and to such the following particulars will convey some idea of its extensive and replete character. Regarding the exterior there need be nothing said since it is the interior of the building that constitutes its importance. The central hall is reached either from the Pump Room, or by the entrance to the old Kings and Queens' Baths by a short passage with a mosaic floor. The hall is a spacious apartment furnished with settees, couches, etc., and is used as a cooling-room for the whole building, care having been taken to make it free from draughts. From this apartment, which serves its purpose in a admirable manner, are entrances to a number of baths and dressing-rooms, in the getting up of which no expense has been spared. In passing it may be observed that all the dressing-rooms are fitted with marble tables and moulded glasses of the date of the first baths, while the bather is able to communicate with the attendant outside by means of an electric bell, which can be reached with ease. A small corridor on the north side of the central hall leads to two dressing-rooms (Nos. 50 and 51), and an Aix douche, giving a varied pressure of water at a required temperature, and also fitted with a shower and feather douche. All the fittings in connection with these are nickel-plated throughout and the bath is intended principally for ladies, as are also dressing-rooms, Nos. 48 and 47, which are attached to a similar but much larger douche bath. The fittings are similar to those in the bath already mentioned only that they are of aluminium instead of being nickel-plated as in the former instance. All the dressing-rooms on this story have a floor of small Diespecker mosaic, and are fitted with oak doors with walnut mouldings, excepting those leading into the central hall, which are of walnut with ebony mouldings. The next dressing-rooms, Nos. 45 and 44, also entered from the central hall, lead into a douche bath 15ft. by 10ft., which is exclusively for the use of gentlemen. These dressing-rooms are laid with ceramic mosaic, and the bath is laid with a tesselated floor by Minton, the fittings being of aluminium as before. It would be well, perhaps, here to describe the method by which the water is delivered for the douche. Two separate supplies of hot and cold water are brought into the bulb in which they mix to the required temperature, this being indicated by a thermometer, the bulb of which is immersed in the mixing liquid. By this means the douche may be applied at any given temperature, according to medical advice. The douche bath last mentioned is elaborately tiled, as indeed are all the baths throughout the establishment, and is so constructed as to form a seat all round. Room No. 43, which is next entered, is devoted to inhalation and for this purpose is supplied with both mineral and spring water, raised to the required heat by passing through a steam chest situated under a portion of the floor, the intricate arrangements of pipes in connection with which gives some idea of how complicated has been the work in this respect. Adjoining this is a room which forms an important feature to the suite of baths. By name it is known as the Humage Room (No. 42). In the centre of the room, the floor of which is composed of handsome ceramic mosaic, is a large walnut table, upon which are ten divisions separated from each other by ornamental porcelain slabs, each division containing an extremely delicate and ingenious instrument for applying the water in various ways. Those in the four end divisions are for application to the

nose, ears, eyes, etc., and those in the six central divisions are for using the water in connection with medicated tinctures, if necessary, for the mouth, throat and respiratory organs. These two rooms may be said to comprise the more special features of the baths, and it is thought that, when their existence becomes thoroughly well known, they will be much resorted to and will prove a source of much remuneration. Room No. 41 contains a reclining bath, a dressing-room fitted with a graduated sofa and glazed screen to enclose the bather while in the bath. Here we have again the mixed douche and feather douche, only the latter is much heavier here than in any of the other baths. Next to this a small corridor, laid with mosaic floor, leads to a lavatory, furnished with hot and cold water and other necessaries, and close to that again we come to a very handsome chamber, with a Pompeian ceramic tesselated floor, and the walls matted with turquoise, blue and white. The bath here is of the usual form of a reclining bath, but it is fitted also with the mixed feather and shower douche, and has in addition a douche for application in cases of lumbago. Special care has been taken to get rid of the steam and vapour arising from the baths, and in other respects the luxury and convenience of bathers have been studied in every possible form.

LOWER FLOOR.

If the baths on this floor are hardly so elaborate as those we have already described, it is due in a great measure to the fact that this portion of the new establishment is a combination of ancient and modern work—that is to say both the architect and builder have been severely handicapped in the obligations laid upon them to leave exposed to view as much as possible the extensive and interesting discoveries of the remains of the Roman bathing system, acknowledged by authorities on the subject to be the finest hitherto discovered in England. The suite of baths on this floor are reached either by a wide corridor running from the central hall, or by a staircase, which latter method of descending is rendered interesting, since it is erected over the old Roman hypocaust, and is so arranged as to enable the visitor to have a complete view of the remains beneath. Descending by way of the corridor, the first to which we come, opening out from this corridor, is No. 38, a reclining bath and dressing room, with a floor of incised tiles, filled in with composition, a very pretty effect, and on the walls a diagonal pattern composed of silver grey and peacock blue tiles. The douches here are the same as we have already described in other baths, but there is in addition a crane lift, which can be used for lifting the patient into the bath either in a sitting or a horizontal posture. This bath has been especially designed for patients who have been ordered to remain in the water for a long time. No. 32 is a new dressing room, in the walls of which may be noticed some very attractive lustre mottled tiles, attached to one of the old baths which has been raised to a similar height as the others, and fitted with metal fittings similar to those already mentioned. The floor here is of white and black tiles, and in a recess attached to this bath are a needle and a Sitz douche, a lave, enema, etc.

We next come to Nos. 33 and 34, which are two dressing rooms attached to a deep bath situated between them. This bath will hold about 800 gallons of water, and besides having steps leading right down into it, has seats all round, and is provided with a hydraulic lift traveller and invalid chair for the use of invalids. In close proximity to this are four baths and dressing rooms (Nos. 36—39), so arranged that they can be let as a suite of baths for a lengthened period. They consist of a dressing room, the floor of which is of white mosaic and the walls of French grey and white, a deep bath with arrangements similar to those previously described, a second dressing room, the floor of which is paved with Minton's herring-bone tiles, and with incised Etruscan and white tiles on the walls, and also a room fitted with a vapour bath, either mineral or spring, needle and shower douche, with hot plates for lumbago.

Working our way round the well-lighted, airy, and spacious passages in a southern direction we cross the site of the hypocaust crushed under the previous building to enter bath No. 24, which consists of a Carlsbad reclining bath, with douche fittings as before, but with one extra spring douche, in order that a cold spray may be given to the patient, and free excess is given all round this bath in order that the patient may be massaed. There are several pieces of ancient Roman work to be noticed in this room, and a door in the west wall leads into another Roman Bath, 33ft. by 20ft., which is really beneath the roadway in Stall-street. At the extreme west of the corridor is a reclining bath and dressing-room, the bath being of the old form for the accommodation of visitors who prefer it to the new ones. This bath is fitted like the others, and in the chamber is a trap door giving access to the Roman work on the north which has not been thoroughly excavated, as the committee did not feel inclined to spend the money which would be necessary in order to make further investigations. For the sake of brevity we may as well say at once that in these baths and passages portions of the old Roman walls are constantly coming into view, and it is here that we have evidence of the immense difficulties with which the work has been surrounded, and which have rendered it so complicated and arduous. In order that the Roman remains should not be interferred with, the very walls remaining have been utilised, and the modern walls rest upon the old Roman foundations; but it is almost impossible to convey on paper the amount of trouble and care which this has entailed, though it will readily be appreciated by anyone making a thorough examination of this portion of the establishment. Turning to the right, upon leaving the bath last described and going towards the south, the chamber which we next inspect (No. 23) is a dressing-room with two different baths, that on the right being an Aix douche for one doucher, with all the arrangements for the douche, glazed screen, etc.; and the second is a reclining bath. Returning again into the corridor, and going up three more steps to enable the floor being placed at a level above the *labrum*, or small bath which was attached to the hypocaust, and which can be seen by raising large oaken doors. Baths No. 22 and 21 on this floor are Ragatz and reclining baths, similar to those already described.

Retracting our steps along this passage we pass an attendants room, similar to that described in the floor above, and this particularly completes the modern work of the building so far as the New Baths are concerned, with the exception of one or two vapour baths of box-like structure, in which a patient may take his seat and have the whole of his body, with the exception of his head, for which an opening is specially provided at the top, subjected to the action of the vapour that rises in full volume direct from the springs beneath, while there are also various means supplied for applying the vapour in other ways. Brief as the foregoing

description is it will answer the purpose of conveying to the mind some idea of the character of the baths and the various uses to which they are adapted. We may add that the main pipes carrying the water over the bridge in York Street from the engine house to the new baths, are large enough almost for street mains, but they are nothing compared to the interlacement of smaller pipes, rendered necessary in order to properly feed the various appliances and instruments with which the baths have been supplied. Everyone will admit that the contractors, Messrs. Long and Son, have done their work well, especially under the difficult task of having to connect a new building with a very ancient one below, and albeit preserving its antiquarian features.

The festivities in honour of the opening of the baths did not end with the luncheon. After the departure of the Duchess of Albany, the Mayoress was "at home," and received her numerous guests. Also in the evening the Mayor and Mayoress held a reception at the Assembly Rooms, to which over 900 invitations were issued. This was enlivened by a concert of vocal and instrumental music. Arrangements were made, too, for the amusement of the people, and the aged poor of the town were entertained at a high tea, so that it was a day of general rejoicing in Bath.

Thousands and thousands of people visit the Continent annually in search of health. They go to Aix-la-Chapelle, Homburg, Wiesbaden, Neuenahr, etc., and many of them are ignorant that within a short distance of their own homes there are waters as powerful for their ailments as any on the Continent, whilst as for scenery and for comfort the English landscape, and the English hotel take the palm. Now that we have at Bath a thermal establishment equal to any on the Continent, we can with an easy conscience recommend our patients who require a course of treatment to give these baths a trial. The maim and the halt, and the rheumatic need not leave the confines of England to seek the doubtful advantages of the foreign cure.

THE CROONIAN LECTURE ON PREVENTIVE INOCULATION.

M. Roux, on behalf of M. Pasteur, delivered the Croonian lecture on "Preventive Inoculation,"[1] in the course of which he had necessarily to treat of the anti-rabic inoculation of M. Pasteur. In order that our readers may know what the exact and latest position of M. Pasteur is, we give the text of that part of the lecture in full relating to hydrophobia. We have italicised a number of lines, upon which we shall offer a short commentary, dividing the lecture into five parts. M. Roux said:

I.—"After all this work upon the prevention of fowl cholera, anthrax, and swine fever had been accomplished, M. Pasteur devoted himself to the study of rabies. When, in 1880, the study of this disease was begun in M. Pasteur's laboratory, the following facts concerning it were alone known: that it was an infectious disease; that the virus was contained in the saliva of rabid animals, and that it was transmitted through their bites. We knew also that the period of its incubation varied from some days to some months, and *here our definite knowledge of its pathology ended.* Many experiments, however, had been made on the subject, but two causes had rendered them especially difficult to carry out and their success uncertain.

[1] See *British Medical Journal*, June 8th, for full text of lecture.

"*Inoculation of the saliva of a rabid into a healthy animal does not always produce rabies, but often has no effect whatever.* Among animals susceptible to the malady, some only become rabid after such a lapse of time that the prolonged waiting, combined with the uncertainty of the results, puts the patience of the experimenter to a most severe test. *The saliva of a rabid animal affords an untrustworthy virus, because it contains a quantity of different microbes, which, when introduced under the skin contemporaneously with the virus of rabies, may prevent the development of this latter, and set up inflammatory processes originated by their growth.* The first thing to do, therefore, was to find some source of the virus of rabies which should be uncontaminated by other microbes. All the symptoms of rabies arise from the disturbance of the nervous system; hence the idea that in that system the rabic virus was specially to be found presented itself to the mind. The previous attempts made, however, to show that the nervous system of a rabid dog was virulent were unsuccessful, because the manipulations to which the nervous matter was exposed in order to inoculate it introduced into it those other microbes which it was essential to exclude.."

M. Roux is a trifle inaccurate about the pathology. It is matter of medical history that we wrote in 1878, and gave strong evidence of the proof of our position, "*that the phenomena of rabies depend on changes in the medulla oblongata and spinal cord, influenced by a specific virus, the modus operandi of which is still involved in obscurity.*" This is matter of little moment; so we pass on to the admission that "inoculation of the saliva of a rabid animal does not always produce rabies." This is what we have been hammering into the public for years. This is why so many persons escape. This is why M. Pasteur's 6,000 patients have escaped; and besides the untrustworthiness of the saliva, there are other conditions which account for non-infection, as protection from clothing, previous waste of saliva on other animals, individual insusceptibility, etc. "*The saliva of a rabid animal affords an untrustworthy virus,*" says M. Roux. But it is this saliva which gives hydrophobia; the saliva is the initial point in the history; the saliva is but too trustworthy on some human beings, under certain conditions. The dog does not leave in the wound "a bit of his brain or spinal cord:" he puts in his saliva. What does it contain? The saliva is the substance on which we want light; and to the saliva, which is the *materies morbi*, we shall have ultimately to return. The products, in the shape of the secondary or tertiary effects, have so far taken the place of the saliva. The saliva has been neglected, and even now we are told that "it is an untrustworthy source." M. Roux continues:

II.—"By inoculating with absolute purity from the spinal cord the brain or the nerves of an animal which had died of rabies, M. Pasteur demonstrated that the *true seat of the virus was to be found in the nervous system.* A portion of the nerve centres of a rabid dog injected subcutaneously into a healthy one will produce rabies more surely than the most active saliva. This demonstration enabled us to take a step forward in its study. The rabic virus being contained in the nervous centres, and the symptoms depending entirely upon that system, the idea naturally followed that the disease only shows itself when the nervous centres are attacked by the virus. Further, that the incubation period is governed by the time taken by the virus to travel from the point inoculated up to the cerebro-spinal axis, and for its develop-

ment therin. If, therefore, the virus be inserted directly into the nervous system, where it has to develop, the incubation ought to be shortened and the disease follow with certainty, because the virus can no longer be destroyed or diverted from its course during its long journey.

"Experiment has fully confirmed this theory, as may be seen from the record of the first dog inoculated by trephining, in which the incubation period was reduced to fourteen days. In fact, any dog inoculated under the dura mater with a little of the spinal cord or brain of a rabid dog takes rabies with absolute certainty, and within a period rarely extending beyond eighteen days. Thus we are delivered from the uncertainties belonging to subcutaneous inoculations, and from the wearines of a long incubation period. After this experiment, the study of the disease went rapidly forward; it was proved that the virus existed in the nerves, and that by that route it travels from the original wound to the brain and spinal cord, and also that it can in some cases be conveyed by the circulatory system. It will be seen, therefore, that the manifestation of rabies may be varied, as the manifestations of the disease in the beginning will depend upon the particular region first encountered by the virus; and, finally, why it is that there are forms of the disease which until now were unrecognised, and which differ from the classic type. The operation of trephining is in itself harmless, when performed with proper antiseptic precautions. It is as successful with the rabbit as with the dog. If inoculation by trephining is performed upon a series of rabbits from the spinal cord or medulla oblongata of an animal which has just died, aud this process is continued with successive animals, we find that the duration of the incubation period, which was at first from fourteen to eighteen days, gradually diminishes. It becomes shorter and shorter as the number of passages of the virus increases, until, at the end of a hundred of the successive inoculations, it has gone down first to seven days, and finally to six. At that point it remains stationary, the rabic virus seeming then to have attained its maximum virulence for that animal (the rabbit), and the virus is said to be 'fixed.' It is from this 'fixed' virus that M. Pasteur obtains his vaccine for rabies by a process similar in several details to that already used for attenuation in chicken cholera, swine fever, and anthrax.

"If in a bottle with an upper and lower tubulure containing below fragments of caustic potash, and closed by a piece of cotton-wool, there is placed a spinal cord of rabbit which has served in a passage series of inoculations, this cord, which contains a quantity of 'fixed' virus, gradually dries preserved from dust and exposed to the contact of the air at a temperature of 25° C., care being taken to keep it at this point. If each day we take a small quantity of this cord, and inoculate on the surface of the brain of a rabbit, we shall perceive that as the cord becomes dry in the sterilised warm air so it loses its virulence. At the end of five days' drying, it will only be capable of killing some few of the rabbits who have received it. At the end of fourteen days, we find it absolutely innocuous after having passed the scale of gradually diminishing activity during the preceding days.

"Having now obtained our material containing the attenuated virus, if we each day inject subcutaneously into a dog a portion of the attenuated cord, crushed in water, taking care to begin the injection with the harmless fourteen days' cord, to go on on the second day with the thirteen days' cord, then the third day with the twelve days' cord, and so on till we reach the cord at zero, or, in other words, spinal cord unattenuated, spinal cord which is deadly—this dog thus inoculated will not die; nay, more, we may try him with the most active rabic virus inoculated into the brain, and he will remain perfectly well, though we know that otherwise intra-cranial inoculation produces rabies without fail. There is, therefore, positive proof that the injections of the dried cord have produced exemption from the disease. The experiment may be repeated as often as you please, but the results remain the same. Dogs which have subcutaneously received the series of cords commencing from the fourteenth day cannot take the disease either from the bites of mad dogs or in any other way. The exempt condition has been obtained in one fortnight.

"Usually rabies remains latent in a dog which has been bitten for a period generally exceeding one month. It might, therefore, be possible to profit by this long incubation period to give before its manifestation exemption from the malady. To elucidate this point, out of a number of dogs bitten by rabid dogs, or inoculated under the skin with rabic virus, some were preserved for control experiments, while the others were subjected to the preventive inoculation of the dried cord in augmenting degrees of virulence. Of these latter, not one took rabies; while of the former, a great number died with the characteristic symptoms of the malady. It was proved possible to prevent hydrophobia even after the bite." In this second part M. Roux goes over ground familiar to our readers, and we need not offer any commentary. Here we admit that M. Pasteur has shown us "how matter in the wrong place" can behave, how by changing conditions a virus is altered, and how soil has an effect upon it—how, in a word, the environment influences the virus. The experiments on the dogs before being bitten are very different from the experiments on man after being bitten; whilst the *modus operandi* must also be taken into account.

As we have repeatedly said, the whole of the laboratory experiments of M. Pasteur have been marked by the highest originality, and he has so juggled with the virus, passing it from one living vessel into another, that he has revealed manifold combinations.

III.—"Notwithstanding, however, the favourable results obtained upon animals, the application of the same method to man was undoubtedly a bold step. By what urgent solicitations and "medical advice" M. Pasteur agreed to take it is a matter of history. In July, 1885, the boy Meister, terribly bitten by a rabid dog, was the first to undergo the anti-hydrophobic inoculation. It is a noteworthy date, and marks an epoch, not only in the history of the laboratory of M. Pasteur, but in that of Science herself. I shall not dwell upon that which is well known; how, after this first successful attempt, persons bitten came to the laboratory from all parts, nor how, since then, each month about 150 persons come to obtain the anti-rabic inoculations. Some among you have been present at these inoculations, and have seen how the emulsions of dried—that is, attenuated—cord are prepared to avoid the introduction of any alien germs. The injections are made in the side on the right and left alternately, and are repeated during fifteen days. For ordinary bites the inoculations start with the fourteenth days' dried cord, and end with that of three days. For more dangerous wounds, those of the head and face, the number of inoculations is greater, and we proceed to the more recent cords more quickly, as it was soon discovered that these last-mentioned kinds of wounds required a more active treatment."

The history of the boy Meister and his protection are very remarkable. The boy was treated by eleven inoculations. Five of these were useless, so that he was really protected by six. The boy Meister was severely bitten; was not treated by the intensive method, which is now said to be required when the bites are severe. During the first period it was no wonder that objections were raised, because many statements were made which were not based on fact, and time has settled their truth. For instance, we were told that patients could come at any time after the bite—even a year; then this was narrowed down to six months; then it came down that even eleven days was too late, as in the case of Lord Doneraile.

IV.—"Since the commencement of the inoculations until now (March 21st, 1889) 6,870 persons have been treated in the Paris Institute alone; and among them many were very severely wounded. The proof of the rabidity of the animal which gave the bite has been furnished either by experiment or veterinary examination in 80 per cent. of the cases. The mortality among the persons bitten by indubitably-rabid dogs and thus treated is about 1 per cent., a very low rate if compared with that of 15 per cent. which usually follows the bites of mad dogs. It is scarcely credible that this extremely small number of failures should have given rise to such violent attacks against this practice; the most contradictory accusations have been brought against it. It was declared to be inefficacious, that its good results were obtained by the treatment having been applied almost entirely to persons bitten by healthy dogs, that the statistics showed *that as many persons had died in France of rabies since the introduction of M. Pasteur's system as before it.* This last assertion was made by badly-informed persons, who took for complete statistics documents allowed to be insufficient even by the very individuals who published them. The proof of the efficacy of the system is to be found by examination of those cases where the rabidity of the attacking animal was incontestably, because experimentally, proved; and above all, from such of these cases as were bitten on the head and face. In this latter class alone it is well known that the ordinary mortality is 80 per cent., whereas among those treated at the Pasteur Institute the mortality does not reach 4 per cent.

"Other adversaries asserted *that the treatment was dangerous*, and increased the probability of death, and thus found themselves confronted with the singular paradox of a dangerous treatment enormously diminishing the death-rate of the disease, and with their previous assertion *that the inoculations produced no result whatever.* These last opponents were furnished in support of their contentions with the violence of their assertions alone, as they had made no experiments whatever.

"Others followed, however, who contended that they had proved by experiment that the foundations themselves of the system were unsound, and that the anti-rabic inoculations could not give immunity to dogs. The fate of these pretended experiments is well known to you. They were shown on unquestionable authority—that of the English Commission charged with the inquiry into the inoculations—to be inexact. You know, gentlemen, of whom this Commission was composed, and in order to answer once for all the whole series of attacks it is only necessary to recall their judgment as embodied in their report—namely, that M. Pasteur had discovered *a method of prevention against rabies comparable to that of Jenner against vaccination.* The absolute nullification of fatal results among persons bitten by mad animals and treated I do not, however, believe to be possible."

The failures after the treatment, if calculated after the manner done by M. Roux, are not so very numerous, but if calculated by other processes, as that of Dr. Prosper de Pietra Santa, are very high. If Pasteur has treated 5,000 Frenchmen, then we must take fifteen per cent. as those who would be likely to contract hydrophobia, and then compare the mortality. Or if we take five per cent. the basis of the English Hydrophobia Commission we must do the same, when we shall also find the mortality high.

M. Roux objects to the criticism which has been made, and which may be summarised as follows:

(*a*) The mortality in France for thirty years—imperfect it may be—gave an annual mortality of thirty per year. This rests on authority of Tardieu, Bouley, and others. If we add to this another thirty for possible cases that may have not been reported we have sixty per annum; but we have no right to assume that the mortality ought to be sixty per year. We cannot alter the whole statistics of a country to suit M. Pasteur's statistics, but we must humour them. Now, since Pasteur began his work the average mortality has been up to thirty, and still more during the years 1885, 1886, 1887, and 1888, it has singularly kept up to this average!

(*b*) The treatment was pronounced as "possibly dangerous" by the Hydrophobia Commission. This refers to the intensive process, and, strange to say, M. Pasteur immediately abandoned it, giving support to this view.

(*c*) The non-intensive treatment was thought to be non-effective, because it produced no effects either on the place or on the system, and the term sterile was applied to it. It neither did good nor harm.

(*d*) The objection was raised that the dosage was not accurate or scientific. It was not measured. Eleven or thirteen inoculations were given at different times. On no theory can this be substantiated. The first injections have not time to do their work before they are followed up by subsequent ones. All is empirical. Hence, such men as Richardson, Peter, and Richards hit upon these blots in the system.

(*e*) The "too-late" theory will not stand. Marinet came under treatment within two hours; he died. If eleven days be too short, as in the case of Lord Doneraile, then it cannot be claimed as useful in the other cases that came over that date. We find in the "successful cases" patients whose bites date back to three weeks. Dissected by the rules of logic the theories and "facts" will not stand examination.

V.—"Nearly all the individuals treated who have succumbed to the disease developed it during the fortnight following the commencement of the inoculation, owing to the fact that in their case the virus passed probably by the blood-stream to the nervous centres immediately after the bite. Indeed, experience shows that the disease may break out from the first (?) to the eighteenth day after inoculation, and it also demonstrates that in cases of submeningeal inoculation it is extremely difficult to outstrip the disease, because the inoculation period is so short that attenuated cord inoculated subcutaneously and far from the central nervous system has no time to do its work. In such cases, therefore, of extremely short incubation period, it is possible that the treatment may fail. Fortunately they are rare, even where the bites have been received in the face. As for the few cases which succumb even where the treatment has been completed and has apparently had sufficient time to produce

its effects, it is extremely difficult to assign the true cause of such failures, but they may perhaps depend upon the special liability of the individuals in question.

"*The most remarkable point, however, in the whole discovery of this preventive inoculation against rabies is that it has been carried out, the virus itself being still unknown. Not only do we not know how to cultivate it outside the body, but, in allowing it to be really a microbe, we can but do so by analogy, for as yet no one has been able to isolate it.* Notwithstanding this, however, it is daily being attenuated and made to pass through the various stages of virulence. Unable to cultivate the organism artificially in flasks and tubes, M. Pasteur has been obliged to do so in the rabbit, and so easily and with such perfect regularity are these cultivations in the living animal performed that they are ready each day for use in the inoculations at a specified time and in the condition of genuinely-pure cultivations. *There is no stronger example of the power of the experimental method applied to medical matters than this one of the prevention of a malady the absolute virus of which is still obscure.*"

The last paragraphs are very remarkable, and absolutely support our views. The cases that died were "infected;" hence they died, bearing out what Jesse Foote said in his pamphlet on hydrophobia in 1793. Foote then said:

"1st.—That every medicine that ever was given for the prevention of hydrophobia had failed.

"2nd.—That although many who have taken medicine have escaped from infection, it ought not to be attributed to the power of medicine, because many have died notwithstanding the use of boasted specifics.

"3rd.—That of many who are bitten, *few are actually infected*, owing to the bite being made through clothing, and that they have escaped by the infecting fluid of the dog being wiped by the teeth passing through the clothing, or by some other fortunate circumstance.

"4th.—That as some medicine or other is indiscriminately given to everyone who is bitten, so every one who is not actually infected by the bite does well, as everyone who is actually infected by the bite dies; and as there are few instances of the latter in comparison with the former, thus it is that the reputation of a cure, by prophylactic or preventive medicines, has been supported, when in fact the safety or danger of the patient has been dependent upon another circumstance, which is whether he was, in consequence of the bite, actually infected or not.

"5th.—That if the patient were not infected he would do well, whether he took any medicine or not; but if he were infected it would be fatal, whether he took medicine or not."

M. Roux admits in 1889 that the nature of *the virus is unknown*, but he gives it as a proof of the value of the method that experiments can be and have been carried on, even in ignorance of what is being used. If this is the "experimental method," then what is the empirical one? or what is the difference? To inject a virus about which you know but little, to counteract a poison about which you know less, is not scientific: it is pure, unadulterated quackery. An apothecary was defined as a man "who poured drugs about which he knew little, into a body of which he knew less." What is the difference between the apothecary and the Pasteurian? The "experimental method" praised by M. Roux is the method adopted by Warner, Holloway, Sequah, and the school of empirics, and thousands and thousands testify to their success, but we decline to class them as scientists.

A FEW SCATTERED NOTES, BEARING ON MEDICINE.

There is a kind of knowledge which all men, more or less, acquire from the long and conscientious pursuit of their callings. It is a seemingly unsystematic knowledge, but it is of great value. I have called it "seemingly unsystematic," because in reality it is not unsystematic; the empirical and valuable facts of experience and practice being parts of as yet unread wide laws. This kind of knowledge is like to the slow discoveries and practices of savage tribes. Savage tribes, all over the world, had discovered the facts of fermentation, the great value of vegetable acids as part of diet, and the value of salt. In other directions, they had discovered that albuminoids in states of putrefaction, were deadly if introduced into the blood; for although they used certain plants with which to poison their arrows, yet it is more than likely that the poisonous influence of their arrows was due to the ferment-like action of putrefactive matter on protoplasm. Some tribes, indeed, used animal matters for their arrow poison. There is room for a work of great value to be written on "The Method and Order of the Evolution of the Early Habits and Knowledge of Savages." Of course, if you are in the society of, and in full sympathy with, the natives of Pekin, Benares, or Odey-poor, you will look upon the English as hardly removed from savages. The highest glory of the grandest city of the world is a vast feed and banquet. The good Mussalman or Brahman looks with horror on such a scene—with far more horror than that of a London or provincial alderman on the cannibal feast of the Solomon islanders! But after all, though the cultured Brahman, and son of Islam, may be horrified at the sight of the city feast, even though Bishops be present—just as the priests are present at the Solomon Islands festivals—yet it appears that the vast aldermanic feasts are evolutions of knowledge and practice in true method of nature. The succession of many different kinds of food, each in small quantity, and each having a considerable interval until the following and different article, affords another instance of the evolution of knowledge from experience, as earlier than our scientific explanations. Another fine instance of this truth is that of alcohol. One may almost say that all tribes and peoples have used alcohol; but science has only in our generation seen the fact that the modes of the alcoholic organic radicals carry their molecular continuity right up through the organic kingdom—fatty acids, aromatics, albuminoids, etc. The British alderman, too, has discovered—though the great teetotal doctors may demonstrate in the laboratory that alcohol arrests the digestion of food—that it none the less reaches the nerve protoplasm, heightens its energy, and really and greatly aids digestion. The farmers always look for their glass of brandy after a roast goose dinner. Such instances I hope may justify my presumption in dotting down some notes of one's own experience.

Digestion.—I am sixty years old, of sanguineo-nervous temperament; have lived some years in tropical countries; always temperate in food and drinks; smoked all my manhood; always an early riser. My habit now is to turn out at 6-30 a.m., and take an hour's walk before breakfast. I cannot attempt to describe the perfect joy of life and being I experience in my morning walk; my best ideas and thoughts come unsought for; it is a comparative daily "new birth." At eight I take a light breakfast of porridge and milk, followed by a slice of toast and butter and a cup

of tea. I no sooner commence eating than all the comfort and elation disappear, and I become as irritable as I was before joyous. Breakfast over, I am in intense misery —my head full and tense, the eyes straining at nothing; the whole body becomes revealed to me, flushed and fidgetty. I then retire to the garden, light my pipe, and solicit the action of the bowels. I always succeed in obtaining relief, though often costive. From the very moment of the first and main expulsion my irritability disappears; I am in an entirely different mood; the previous bursting fulness of skin and nervous system instantly disappears, and I am calm and quiet.

How does my simple breakfast transform my being—mind, feelings, and body—from joy to misery? Sir W. Aitkin ("Animal Alkaloids," p. 10) says that Bouchard " . . . finds that the poisonous activity of even healthy human fœces is very great, and a substance obtained from them by dialysis produced violent convulsions in rabbits." But this class of causes will hardly apply in my case, for it is only when I take in new food that the suffering comes on. I have always viewed the symptoms from the nerve side, that the nerve system of the whole body is involved, and contributes toward the reflex action of the expulsion. Though the sphincters and abdominal muscles are the more immediate agents of expulsion, yet the general nerve system is involved; and hence, in constipation we, as a basis of treatment, seek to invigorate the general health and system. I believe that it is a calamity to any young man when he begins the habit of smoking; but having acquired the habit, and to those especially who may have spent some years in India or the tropics, where full exercise and the evolution of vigour is hindered, a pipe smoked whilst soliciting a motion is a very great aid.

To continue my own case—after the relief of the bowels, I am well all day; but the pipe, for an hour or two, takes off the spontaneity of the mind and the power of study. At 2 p.m., I take lunch of tea and biscuits, or a very light rice pudding. At 6-30, I go out for an hour's walk, and when empty and in the fresh air, my intellect is again at its best; its spontaneity returns, and I can frame philosophical argument, or follow the continuity of deeper science or pathology. At 7-30, I dine, and do so with nothing short of dread. Immediately on eating, the mind becomes irritable, the skin all over the body seems to flush and to be fidgetty. The dinners which agree with me are boiled corned beef, or fish, or "finny-haddy." I also often dine on curry and rice, or a plain baked rice pudding, and which agree. I have proved the suitableness of boiled corned beef, and even of sailors' junk, to my case for over thirty years. I can also enjoy a dinner of boiled onions, or fried onions, and both agree with me. Pickled onions, and plenty of malt vinegar on my vegetables, agree well. Since reading Sir W. Aitkin's "Animal Alkaloids," I have thought whether or not my case is somewhat allied or parallel to the following:—"Some time ago, Dr. Lauder Brunton pointed out the resemblance between the languor and weakness which occur in many cases of indigestion, and the symptoms of poisoning by curare, and drew attention to the probability that the languor was due to the effect of poisonous substances absorbed from the intestine" (*op. cit.*, p. 27). In those cases of "indigestion" which have "peculiar symptoms—namely, of a sense of weight in the arms and legs, as if they were lumps of lead, . . . recent researches . . . render it very probable that peptones are the poisonous agents in these cases—a conclusion confirmed by Dr. Lauder Brunton's observation that 'the weakness and languor are apparently less after meals consisting of farinaceous food only'" (*op. cit.*, p. 26). I have notes of hundreds of young people, phthisical and pre-phthisical, who have told me of their almost passion for onions and salted meats, and that such foods agree with them. For many years I have usually prescribed muriatic acid and quinine for indigestion. It is quite rare for the patients not to say that they are greatly benefited.

The importance of acids in our diet has perhaps not been sufficiently considered. In India I have had native women clinging around my legs, and beseeching for limes and tamarind. If you issue a week's ration of pickles and vinegar to a "mess" of eight Irish peasant girls, they will eat them right off at once. When I see good results from muriatic acid in cases of indigestion, I am conscious that the therapeutic action is one of infinite complexity. The explanation will probably fall within the range of those vito-chemical studies on the animal alkaloids, etc., which have been opened up in this country by Dr. A. M. Brown, Dr. Lauder Brunton, and Sir W. Aitkin. Can it be that muriatic acid, taken after meals, or lemon juice, lime juice, tamarind, etc., taken with and after meals, may arrest the evolution of poisons out of the albuminoids of our food? How does lemon or lime juice cure the chronic dysentery and diarrhœa of natives of India? Many hundreds of times I have seen the natives of India improve and get well of old dysenteric diarrhœa under the free use of lemons and limes. In vain are the astringents used in such cases, but limes will often cure. How? To say that the native is scorbutic is no answer. We want to know the nearer vital mechanism of the action of the vegetable acids, etc. Does the all-essential salt of our diet also have a like effect? Is it from the action of the salt on the animal tissue that corned beef agrees with so many constitutions, where fresh meat is followed by indigestion? The ration of salt to natives of India, when fed by Government, is one ounce a day. Natives will consume a large amount of salt, if they can get it. It seems likely that the capital effect of Carlsbad, Fredrichshall, etc., when given far short of purgation, may be due in part to the common salt which they contain. Have these facts of practice any correlation with the arrest of the evolution of poisons in the intestines, stomach, etc.?

Costiveness.—I constantly have noticed, during the past ten years, that I am painfully costive during easterly winds. This is not to be explained by any easy hypothesis of evaporation. I have lived in the interior of continents, in tropical and sub-tropical latitudes, and which were subject to terrible hot winds. The wet and dry bulbs used to register a difference of 16° Fahr., but I did not suffer from costiveness. I think that the explanation must be sought in that, over fifty years of age, the pan-cellular vital energy is less evolved out of my protoplasm than of yore; and that in some way, not yet capable of expression, the east wind exhausts my vital organic energy. Every function of the body is, in a very great degree, dependent on, and correlates with, other functions. Mental shock has precipitated those poisons out of protoplasm whose results are cholera and yellow fever. Sudden diarrhœa, and the evolution of horribly putrescent gases, often follow mental shocks; and east wind in 50° north lat. is, in some way or other, a shock to the exquisite equipoise of the essential correlations on which health depends.

Alcohol.—There is no body in nature of greater interest than alcohol; it is the first product in the splitting up of

the molecular bonds of the carbo-hydrates; it has an absolute molecular continuity with a large proportion of the matter of which living plants and animals are composed. There is an *à priori* presumption that it must be a most powerful agent over protoplasm, a conclusion which is fully borne out by the experience of mankind. Our difficulty in practice is that nature in health and in disease is so complex and cosmic in her correlations, and these correlations are so unknown to us, that we are ignorant of the precise occasions when we may apply the molecular energy of alcohol wisely and fittingly.

We may not be disposed to fully agree with Dr. C. B. Klunzinger when he says of the Copts of Upper Egypt:[1] "He never tastes his evening meal until his mind is clouded by the vapours of this water of life, which he prepares for himself from dates. To this spirit alone he owes the rotundity of his body, and perhaps the existence of his race, which would otherwise have died out long ago under the regimen of peas, beans, and fish, without fat or butter. . . ." But we cannot ignore the fact of the use of alcohol by most of the races of mankind. Whatever evils may result from the use of alcohol, its almost universal use must indicate not only some great power, but also some good. There is, however, no social phenomenon in this world so sublime as that of Islam in its abstinence from alcohol.[2]

But I am viewing alcohol purely as a medicine, and not from the grand religious and social aspects of Islam.

One of the worst features in the history of the medical mind, in the past and present, is the practice of reasoning from "affirmatives." "A few times hitting countervaileth many times missing" (*Bacon*). It must always be a distress to thoughtful minds to hear and read positive assertions on the cure of cases, by this and that drug, and to no drug do these remarks apply with more force than to alcohol. I know that alcohol has a deep molecular continuity with protoplasm, and I hold a vague and approximate hypothesis that alcohol is capable of arresting the catabolic devolutions of protoplasm into "poisons;" but such an hypothesis would not carry me into the heroic administration of brandy in typhoid.[1] Such a practice would not scientifically flow from the hypothesis, even if the latter had much of truth for its base. Unlimited scepticism in therapeutics is as unwise as are the baseless assertions of our supposed "cures." But in reference to alcohol, I have been constrained to hold that often, when freely taken, on and at once after, chill, it has warded off both inflammations and fevers. How it acts thus science does not yet reveal. We may, however, ask hypothetically, Does it arrest the devolution of protoplasm into poisons? Does it act by exciting the polarity and energy of the ultimate molecules? Could we but work out the vital mechanism of the action of alcohol on living protoplasm, we should be on the method of all other therapeutic actions.

In my own case, although I enjoy the moderate use of wine and other forms of alcohol, yet in the after stages—say six hours after—my system is painfully irritable. I have given up its habitual use for so many years that I have lost all desire for it. Nevertheless, I take it now and then, as a medicine, and am compelled to hold the opinion that it is a medicine of unsurpassed value, *e.g.*: Two winters ago I went out at 11 p.m. to post a letter across the street, with only a thin coat on. I fell in with a man who was in an extreme degree "leg-drunk." He made constant endeavours as he went on the road to cross and recross, and falling repeatedly with extreme violence flat on his abdomen and chest. In that position he would lie for a minute or two motionless. For over an hour I followed and watched him, until I found the police and saw him taken to a place of safety. I was shivered and cold "to my very bones;" when I reached home my abdomen was extremely distended. I felt that I was going to be ill. I drank two stiff glasses of hot whisky and water; felt the distension and shivers subside; enjoyed my pipe and book, and was all right next day. Many years ago I was sent down to report medically on a district of the Schawn River, Trinidad, West Indies. It was a notoriously sickly region. I left Port of Spain by steamer at about 7 a.m. The negroes who took me off the steamship with their boat, at the mouth of the river, managed to ground in the mud banks, so that we did not really enter the river until about 6 p.m. In the meantime, repeated showers from the mountains had wetted us, and we were as often dried by the blazing sun—conditions altogether admirably adapted for the evolution of fever. A short distance up the river I saw a wooden shanty, and in the window recognized the open hand and yellow label of Allsopp's pale ale I thoroughly enjoyed a quart bottle of that drink; proceeded on to the sugar estate to which I was bound; stripped and

[1] "Upper Egypt: Its People and its Products." London. 1878. p. 90.

[2] "Mungo Park, in his travels seventy years ago, everywhere remarked the contrast between the Pagan and Mohammedan tribes of interior Africa. One very important improvement noticed by him was *abstinence from intoxicating drinks*. 'The beverage of the pagan negroes,' he says, 'is *beer and mead*, of which they often drink to excess; the Mohammedan converts drink *nothing* but water.'"—("Park's Travels," chap. ii.)

King Cetewayo, of Zululand, spoke thus to a deputation from the British National Temperance League, which had waited on him when he was in England: "I can only say that, as a nation, my people are, so to speak, abstainers; or, at all events, they are not accustomed, nor do they as a people partake of spirituous liquors. . . . But I think that the right place to shut the door is the side from which the spirits come. It is no good my shutting the door on my side, for I have no distilleries. But I think the proper way would be for the Natal Government to assist by placing restrictions upon the introduction of spirituous liquors into my country."

"The Rev. A. Day, of the Lutheran Mission in West Africa, with pathetic indignation, says 'The vilest liquors imaginable are being poured into Africa in shiploads from almost every quarter of the civilized world. On one small vessel, in which myself and wife were the only passengers, there were in the hold over 100,000 gallons of *New England rum*, which sold on the coast for one dollar a gallon in exchange for African produce."—(Quoted from "Christianity: Islam and the Negro Race." By Edward W. Blyden, LL.D. London: Whittingham and Co. 1887.)

The late Dr. Blyden was a negro of pure blood. His work, above quoted, indicates a mind of extraordinary power, wide grasp, keen sympathies, and just judgment. The book will enlarge the mental horizon and concepts of those who may have the privilege to read it.

[1] One cannot but be startled at the difference of practice in fundamental matters. Dr. J. Curnow, at King's College Hospital, gave 310 ounces of brandy and fourteen pints of champagne to one patient in typhoid. To another case of typhoid he gave two gallons, three pints, and eight ounces of brandy, and twenty-one pint bottles of champagne (*Lancet*, January 1st, 1887, p. 11). On the other side, the London Temperance Hospital gives capital results of the treatment of typhoid without alcohol. Statistics of results from different hospitals are about valueless for deciding such questions. There is no *à priori* ground for not giving alcohol. Alcohol is that body in nature most near to carbohydrates; it is the most assimilable of all bodies. But, besides, it has a special power over, or correlation with, protoplasm. That it heightens the energy, mind, senses, feelings, and functions, proves that it affects the modes of the ultimate protoplasm and cell-contents. Granting that alcohol can temporarily arrest the catabolism of protoplasm after chill into poisons, would it follow that its administration in protracted typhoid would be based on the same principles?

had a good shampooing by East Indian natives; took a glass of rum and water, and was perfectly well.

A review of one's experience will recall many cases of men in the prime of life, and in *apparent* perfect health, whose fatal illnesses commenced with rigor. Chill, or rigor, is by no means a simple thing, nor can the subsequent congestive pneumonia, pleurisy, or cardiac affection be explained by any mainly mechanical theory. "Chill" may involve, in certain cases, a devolution of protoplasm, and the evolution of poisons within the ultimate molecules.

Chill or rigor seems to be a fundamental fact in pathology. It is the first recognizable stage of many fevers, of inflammations, of febro-inflammations—such as epidemic or sporadic bronchial fever, epidemic pneumonia, cynanche tonsillaris, herpes, etc. Rigor often ushers in fatal cases, to which no name can be given—*e.g.*, I have seen rigor followed by irrecoverable disturbance of cardiac function, without inflammatory signs; by slight pneumonia at apex, extreme vomiting of bile during many days, slight delirium, drowsiness, and death. No localizations explained the symptoms or fatal result. Rigor is the first recognizable sign of "blood-poisoning" (so-called) and its terrible resultant series after parturition. Rigor ushers in bronchitis, pneumonia, pleurisy, etc., whose deeper pathology is related to that of fever. We are entitled to advance the hypothesis that rigor indicates a vito-chemical change in the modes of the ultimate protoplasm, and that such change is recognized and made manifest in the system, by and through the fundamental irritability of protoplasm, and by its subsequent higher nerve differentiations. That alcohol can under certain conditions, and at certain times, arrest the catabolism of protoplasm into other modes (poisons), is thus both consonant with the facts of observation and with vito-chemical theory. But the fatal or potential rigor, which is followed by so many different diseases (so-called), implies a prior state of unstable equilibrium of protoplasm, or a lower mode of its energy—*e.g.*, I have rounded the Capes of Good Hope and Horn, say thirty times, both in winter and summer. I never clothed up heavily, and cared nothing for drenchings by the tops of the mighty waves, which dashed on board. But I never took cold. I have carelessly slept through the tropics, on the stern lockers, with the stern-ports open, and never took cold. But now if I get in the slightest degree damp, or feel the slightest draught of air, I get a violent and persistent sneezing, which is followed by catarrh. I know that were I to take a voyage again, I should enjoy at sea my old immunity from catarrh. I refer to my own experience, but it applies generally. The system, at sea, does not take cold. There is a popular saying that "Salt water wettings never give colds." Whether sea water has any potential difference in its correlations or power of conduction to the energy of the body than has fresh water, or whether the powers of resistance to disease are greater at sea, we cannot decide; but all who have been much at sea, and who have had grave duties, will know that the system experiences at sea, both in mind and body, an energy and elasticity very different from the tamer modes of shore life. These examples will serve to point to the major factor of most diseases—viz., the recurrent unstable equilibrium of protoplasm, which makes the rigor a potential power toward disease.

It seems just to hold the hypothesis that alcohol, taken sufficiently early and in sufficient amount, will often arrest the devolution of protoplasm into poisons. I think that I have seen exhausted and worn women who, after parturition, were developing into rapid and irregular pulse, slight delirium, sleeplessness, and a grave malaise, saved by the free administration of alcohol. I formed hypotheses in such cases that the alcohol had arrested the catabolism, or reversion of protoplasm, into poisons. But here I must recall Bacon's caution of the danger to truth of reasoning from "affirmative instances." M.D.

SOME QUACK REMEDIES.

By an Analytical Chemist.

In the course of our professional visits, and especially in hastily opening drawers and cupboards in search of something or the other of which we have urgent need and usually find there, we come across bottles or boxes which we glance at with a half smile, and then overlook with diplomatic presbyopia; for they are quack remedies and nostrums of which our patients of the better class have usually grace enough to be ashamed, and yet the weakness to almost believe in. I have lately confiscated—*con permiso*—a few of these and analysed them with the aid of microscope and test-tube, and the results are from their grotesque absurdity, worth (shall we say) pillorying. "Warner's Safe Cure" I find to be a tincture of the two wintergreens, *Pyrola umbellata*, a remedy for renal troubles described in Christison's Dispensatory of some years ago, but long since relegated to the limbo of feeble inefficiencies; and of *Gaultheria procumbeus*, with a little glycerine. It would be harmless, but the "cure" contains so much spirit (rum?) that it would do serious mischief in true cases of Bright's disease, and is so pleasant to take as a dram that I suspect that is its chief attraction. The water-bath residue deflagrates, from the presence of nitrate of potassium, a collateral proof that it is a tincture of the plants, and not merely spirit flavoured with the essential oil of the latter.

A couple of "Holloway's Pills" yielded nearly equal parts of Cape aloes and potato starch, with a little powdered licorice root, the latter ingredient giving me little trouble in its identification. "The Ointment" I have not seen a sample of. "Beecham's Pills" are Cape aloes and potato starch again, pure and simple, and, as the striation of the latter is obliterated, the mass must be rolled out after heating. One pound of it would cost something less than sixpence and would make about twelve dozen boxes, worth "a guinea each," and although they are generously given away for a shilling, we can understand how the artistic advertisements are paid for.

"Mother Siegel's Syrup" is aloes dissolved in treacle. South Africa seems to be the happy hunting ground of the quack; all the pills are Cape aloes with something to harden it. Morrison used cream of tartar, but potatoe starch is now preferred. "St. Jacob's Oil" is a solution of camphor in oil of turpentine, with a few drops of oil of cajeput, and some colouring matter. "Elliman's Embrocation" contains four parts of dilute acetic acid, two of colza (?) oil, one of turpentine, and, I believe, one of mucilage; but I had only a single teaspoonful to experiment upon.

"Steedman's Teething Powders" are a mixture of one part of calomel with five of wheat starch, and a trace of opium, enough, however, to yield the microscopic proof, and the meconic acid reaction in a single powder. "Clarke's Blood Mixture" is a solution of iodide of potassium in coloured and sweetened water, but there was so little left in the bottle that I could not—without more trouble than it was worth—determine the quantity. "Eno's Fruit Salt" is

our old friend the seidlitz (Seignette's) powder with a little sulphate of magnesia and sugar.

Another article which is turning the most inoffensive illustrated papers into hideous pitfalls is "Brooke's Soap," which is ordinary soap with about one fourth its weight of a fine, but very hard, powder, which the polariscope shows to be crushed flint. Its use will be greatly to the advantage of the manufacturers of tin ware and plated goods. "Pear's" is a resin soap dissolved in spirit during its making, mixed with sugar, and, I think, a little castor oil. An excellent detergent for any but delicate skins.

"Tamar Indien," a confection of senna in a very convenient form. "Minns's Fire Grenades" contain three ounces of common salt and one of sal-ammoniac, dissolved in water. I have only this morning came across the absurdly named "Salt Regal"—if the deviser had only had Latinity enough to call it Sal Regalis!—itself only "Eno's" and the older seidlitz again, but with the ingeniously trifling addition of a trace of permanganate of potassium. I find that one tenth of a grain of Condy's crystals added to a dessert-spoonful of seidlitz powder gives a snow-white saline, and yet a lovely pink colour to a pint of water, and is identical with the last new specific for every ailment, from flatulence and heartburn to cholera and diphtheria! This, however, is all in the way of trade, and unblushing mendacity is the primary element in the art of puffiing. But, as anyone with the most rudimentary knowledge of chemistry would detect the trick in a moment, and the mere tasting of the weakest solution of the permanganate would show that only the most inert trace could be used as a colorant, what must we think of the distinguished analysts' testimonials? The first is an admirable specimen of what is said to be the chief use of language: the G.O.M. himself could not have written as many words with less meaning; the writer of the second commits himself to a statement which is utterly unjustifiable, and all three will influence the beliefs of the ignorant people who buy quack remedies. Truly "*Veritas vel mendacio corrumpitur vel silentio.*"

THERAPEUTICAL NOTES.

From our Berlin Correspondent.

Creasote Treatment of Tuberculosis of the Lungs—Multifarious ways of applying Ichthyol—Chromic Acid against Sweating of the Feet—Hydracetin, the pure Pyrodine—Naphthalin in cases of Typhoid Fever—Agaric Acid.

Dr. E. Holm, of Greifswald, publishes in the *Therapeutische Monatshefte* the results of his extensive experience of the *Creasote Treatment of Tuberculosis of the Lungs.* Creasote forms a very powerful antiseptic and germicide; and it is therefore only natural that it should be recommended to combat a disease which is undoubtedly of bacillary origin, and which ranges within the wide class of infectious diseases. It is impossible to give separate accounts of all the different cases which Dr. Holm treated with creasote; but it will be interesting to hear the summary report of his cases, and the conclusions he drew from a very extensive use of the drug.

1. Creasote is best prescribed in the form of gelatine capsules, or in combination with tinct. gentian. Both forms were mostly given without the slightest discomfort arising, if the precaution was observed to administer the drug after each meal, and to commence the treatment with small doses. Sometimes the appetite was even improved. Patients were soon accustomed to the peculiar taste of the remedy, and never was the taste a reason for its continuous refusal. That the patients should long for it with eagerness, after they have taken it for some time, has been stated by many authors, but could not be confirmed by Holm's cases.

2. Creasote has no influence whatever on the diarrhœa caused by tuberculous intestinal ulcers, nor did it improve any existing constipation.

3. Abatement of temperature by the action of creasote is questionable.

4. In twelve cases the decided improvement in the conditions of the patients was undoubtedly and solely due to creasote. In the remaining eighteen cases (thirty forming the total of the cured and improved cases) the success was conjointly due to creasote and to the favourable change in the outer conditions of the patient, he being removed from unhealthy localities, and placed under the wholesome *regime* of a well-managed hospital. The first twelve cases, however, had been in such good hygienic conditions before transference to the hospital, that the improvement cannot be accounted for by the change of outer circumstances.

5. Admixture of streaks of blood to the sputum was favourably influenced by the creasote, as such traces of blood completely disappeared, the sputa at the same time becoming more scanty. The effect of creasote in cases of real hæmoptoë could not be properly studied, as in all such cases other remedies and measures were conjointly employed.

6. Bronchial secretion and cough gradually lessened; the sputa persisted in containing tubercle bacilli.

7. The effect of the drug was proportionate to the quantity of creasote introduced.

8. In far advanced cases of pulmonary tuberculosis, the administration of creasote is totally inefficacious.

9. While in incipient and in such chronic cases where no great destruction has taken place, its use is greatly to be recommended.

Dr. Holm availed himself of the following formula:

℞ Creasoti.
Tinct. gentian.
Spirit vini rectif.
Vin Xeres q. s. ad colat.

M.S. One tablespoonful to be taken two or three times a day in a wineglassful of water.

℞ Creasoti.
Æther acet.
Tr. aromat.
Syr. simpl.
Aquæ dest. q. s. ad.

M.S. One teaspoonful three times a day in half a tumblerful of water.

℞ Creasoti.
Tr. gentian.

M.S. Five drops to be taken three times a day in a tumblerful of milk, the dose to be increased gradually.

The *Therapeutische Monatshefte* contains two interesting and independent communications on the therapeutic *value of ichthyol.* Dr. von Hoffmann and Dr. Lange, of Baden-Baden, have for the last three years extensively prescribed and applied ichthyol in their private practice, and at the out-patient department, which was largely frequented by an

urban public, as well as by people from the surrounding country districts. With regard to the internal administration of ichthyol, they recommend pills and capsules fulfilling all the requirements of a refined taste; while for ordinary practice, appropriate corrigentia and vehicles may easily be found by referring to the chemical and physiological properties of ichthyol. Occasionally, but very rarely, patients are met with who *bonâ fide*, and after deliberate trials, energetically refuse to take the remedy. They are the same patients who also cathegorically object to cod-liver oil.

Generally speaking, ichthyol will excel in all cases of abnormal formation of gaseous products of the intestinal tract. Patients who are much troubled with "winds," and who ascribe all kinds of nervous complaints to the said slight disorder, often not only exhaust the physician's patience, but also the number of drugs available for this ailment. Such patients will derive great benefit from ichthyol. Also in cases of gastric and intestinal catarrh, ichthyol is very reliable. Its use in the out-patient department, and in all cases which are not constantly under the control of the physician, is greatly facilitated by its being non-irritant and non-poisonous. Dose and form of prescription have to be shaped according to the requirements in each case. Patients suffering for years from rising of gas after meals, and also patients who only suffer from the effects of temporary abnormal fermentation in the stomach, will be cured by a single dose of ichthyol given in a large quantity of water.

In some country and mountain districts there exists a kind of scrofulosis which is not caused by poverty, bad dwellings, insufficient food, but by an irrational system of nursing, want of cleanliness, and over-feeding. Such children present swollen lymphatic glands, all kinds of eczema, chronic inflammation of the eyes, flatulence, and copious stools of characteristically repulsive smell. Formerly it was customary at the clinic of Greifswald to treat such children with repeated baths, washing of the skin with carbolic or corrosive sublimate, or creoline soap, and an occasional single dose of calomel, repeated perhaps once a week. Now such patients take a mixture of ichthyol, alcohol, and spirit æther, āā. One drop of this mixture is twice given to a one year's child, two to a two years' child, etc. Already, after the second day, the change is very remarkable: flatulence and repulsive smell of the fæces have gone, and the children begin to show a more healthy appearance.

Ichthyol applied to wounds is an excellent hæmostatic. It also secures healing by first intention. The result is a fine, hardly-visible cicatrix. Therefore, wounds of the face, fingers, or hands, cannot be better treated than by making use of ichthyol. For treating burns and colds there is nothing equal to the beneficial action of ichthyol, which is equally spread over all affected parts of the body. Cases of acute rheumatic fever, with relapses and weakened constitution, do splendidly under ichthyol treatment (the remedy being given internally and externally), and a state of health is speedily attained, which never found its equal under any former treatment. The full action of ichthyol is best obtained by prescribing the above-mentioned mixture of ichthyol, alcohol, and spirit æther. The appropriate number of drops is diluted with a wineglassful of water, taken before meals, and followed by a cup of tea or coffee, or a plate of soup. Repeated analyses, indicating the percentage of nitrogen, confirmed Zuelzer's results. They also prove that Riedel's thiol, although resembling ichthyol in its external appearance, is devoid of the specific action of the latter.

Dr. von Brunn, of Lippspringe, reports on the very favourable effect of the ichthyol treatment in cases of *Erysipelas*. In consequence of the recommendations of such high authorities as Unna and Nussbaum, he resolved to try it in this particular disease. The governess of his own family was subject to erysipelas, and was first treated by external applications of salicylic acid ointment; but to no avail. The disease was progressing rapidly, when he began to paint the parts next to the affected regions with ichthyol collodium, ammon. sulph. ichthyolic æther āā 3 i. collod. 3 ii. Afterwards, also, the erysipelatous skin itself was treated in a similar way, with the effect that in the course of the same day the treatment was commenced, spreading was stopped, infiltration of the skin subsided, and evening temperature went down to 98.4° without the assistance of any antipyretics.

The Medical Department of the German Ministry of War recommends *Chromic Acid* as a cheap, reliable, and non-irritant remedy for the radical cure of disagreeable *sweating of the feet*. According to the official publication, the application is performed in the following way: A forceps, armed with some absorbent cotton wool, is dipped into a 10 per cent. solution of chromic acid. Then the soles of the feet and the adjacent parts of the toes are painted with it. In severe cases of feet-sweating, the painting is repeated every two or three weeks, in less severe cases every six to eight weeks. If open sores should exist, it is preferable to use first a 5 per cent. solution, which is followed by the application of the 10 per cent. solution as soon as the complete integrity of the skin is restituted. It happens sometimes, especially during the hot season, that the general perspiration of the body is greatly increased after the application. But this abnormal secretion passes off after one or two days, without causing any discomfort whatever.

Some time ago, Professor Dreschfeld, of Manchester, as will be remembered, published an interesting account of his clinical experience with a new antipyretic, called *Acetylphenylhydracin* or *Pyrodine*, but the author himself soon found out that the new preparation was not a chemically pure substance, but a mixture of several preparations. Professor Liebreich, who took the matter up, administered the substance to children and adults, the doses being half to one grain for the former, and two to three grains for the latter. Both authors are not entirely satisfied with the results, and it was therefore only natural that chemical industry endeavoured to obtain perfectly pure acetylphenylhydracin, or at least chemical compounds containing the essential complex atom:

$$N \begin{cases} H \\ C_2 H_3 O. \end{cases}$$

The latter was thought to play the most important *rôle* with regard to the antipyretic action of the drug, which suggestion seems highly probable, because the two well-known antipyretics—antifebrine and phenacetin—contain the same group of atoms.

Professor Guttmann has now quite recently obtained such a pure acetylphenylhydracin, abbreviated to *Hydracetin*. This new, pure substance represents a white, tasteless, and odourless powder, consisting of finest crystalline scales, which are soluble in fifty parts of water, readily soluble in alcohol. Guttmann publishes pretty favourable results with this new substance in eight cases of rheumatic fever, two

cases of sciatica, and eighteen cases of various febrile disorders. The dose administered never exceeded two grains, and the treatment was never continued for more than three days, showing that great caution is required with this new treatment.

Pyrodin has highly reducing properties; it reduces a solution of nitrate of silver, also an alkaline copper solution. It discolours permanganate of potash. For reason of this reducing property, pyrodin has been applied in cases of psoriasis, substituting chrysophanic and pyrogallic acids. It has one advantage over the latter acids—namely, not to stain linen or skin.

"*Naphthalin in cases of Typhoid Fever*" is the subject of a lengthy communication in the *Berliner Klinische Wokenschrift*. Dr. Schrwold, induced by Professor Rossbach, extensively experimented with the drug at the internal clinic of Jena. His experiments confirm Rossbach's statement that naphthalin is well worth trying in cases of typhoid fever. He, in this respect, contradicts the communications of Furbringer.

Dr. Klemperer reports to the Society of the Charité Physicians of Berlin on the action of *Agaric Acid* in cases of night sweating of consumptive patients. Agaric acid is prepared out of agaricin, the latter forming the active principle of *Agaricus albus*, a drug much used in former days. Agaricin, which was much in fashion some time ago, has again been given up by reason of its uncertain composition and strength. Klemperer administered pills, each containing one-sixth of a grain of agaric acid, and had great success with treatment, even in cases of most profuse sweating. One pill is given at six p.m., followed by others up to five, if one alone should not be found sufficient. The remedy does not cause any unpleasant after-effects. It is said to be efficacious, even in cases where atropin was of no avail.

Clinical Cases.

The following plates are taken from photographs shown by Mr. Edward L. Freer in his paper "On the Surgical Aspects of Rickets," which appeared in the Provincial

Case 1.—Ethel Price—On Admission.

Medical Journal, May, 1889. The results obtained in each case can be appreciated by comparing the children before and after operation.

Case 1.—Ethel Price, æt. seven, was admitted into the Birmingham Royal Orthopædic Hospital on October 11th, 1887. Before operation the child's condition can be seen from Photo 1. She was suffering from double genua valga (rachitic). McEwen's osteotomy was performed October

Case 1.—Ethel Price—Cured.

14th, and she was discharged from the hospital on December 10th, 1887, in the condition shown in Photo 2.

Case 2.—Arthur Hills, æt. four, double genua valga (rachitic); admitted March 10th, 1888. Osteotomy March 14th. The appearance of the child before the operation is seen in Photo 1. The child was discharged on April 28th, 1888, in the condition shown in Photo 2.

CASE 3.—Emily Sewel, æt. three years, general rachitis, lateral curved femora, and anterior and lateral curved tibia and fibula. It was considered inadvisable to attempt osteotomy, as it would have required so many operations, and instruments were applied. As can be seen from Photo 1 her condition was most miserable; but after patient treatment for four years with instruments only, she was brought into the condition now seen in Photo 2.

CASE 2.—ARTHUR HILLS—ON ADMISSION.

CASE 2.—ARTHUR HILLS—CURED.

CASE 3.—EMILY SEWELL—ON ADMISSION.

CASE 3.—EMILY SEWELL—CURED.

Reviews.

The Causes and Treatment of Abortion. By Robert Reid Rentoul, M.D., with an introduction by Lawson Tait, F.R.C.S. Edinburgh and London: Young J. Pentland.

This work is an extension of an essay "on the causes and treatment of abortion," which obtained a prize of £20 offered by Dr. Ward Cousins in 1886, and as to the value of the work we have already the opinion of Mr. Lawson Tait. "As an exhaustive discussion of a special branch of medical literature I have seen nothing better in the English language, and the clearness of its expression as well as the precision of its conclusions, place it far above the kind of productions with which we are favoured in most other languages than our own." Let us see in what way it has deserved this approval. The work is divided into eleven chapters as follows:—Definition and pregnancy, historical notice, the causes of abortion maternal, the causes fœtal, the causes paternal, criminal abortion or fœticide, abortion in plants and animals, the symptoms of abortion, diagnosis and prognosis, complications and sequelæ, treatment, besides an excellent bibliography, index of authors, and general index. In the historical notice Dr. Rentoul deplores the tendency of the age to regard fœticide as hardly a criminal offence, and, as he truly says, the profession should take the matter up for the moral tone of a nation can be sustained and elevated by the members of the medical profession. The various causes, apart from criminal ones, which leads to this accident are admirably described and leave little to desire, and as there are some excellent illustrations the text is made clearer. The complications, as is well known, are numerous: pelvic cellulitis, peritonitis, acute metritis, endometritis, salpyngitis, ovaritis, phlegmasia dolens, pulmonary and arterial thrombosis, tetanus, prolapse of the ovary, secondary hæmorrhage, may follow, all which conditions are fully described and appropriate treatment suggested. There is a very excellent chapter on fœticide, and it appears lamentable that Dr. Rentoul should be able to write "the multitude of drugs bought of the druggists, so that the buyers may bring on their periods must be legion; the frequency with which the uterine sound is used must also be a prolific source of evil. Women at present go from one hospital to another every so long, that some one of the staff may examine their wombs. Cases are known when such women have reminded the practitioner that he did not examine them in the same way that another medical man had. The uterine sound is a very powerful instrument of danger. Does its utility outbalance its harm. Cannot two well trained fingers get on well without it? The ordinary gum elastic sound, an instrument which allows a woman to procure abortion on herself and by her our help is well known. It is said to be an American instrument; but of this I am cognisant that it lies on an instrument makers shop counter for sale, and is often sold by him. I think lecturers on medicine and on diseases of women do not sufficiently impress on their students the danger of their in any way incriminating themselves by useing uterine instruments where there is the very slighest suspection of pregnancy existing." In the historical notice Dr. Rentoul has accumulated a mass of evidence which forces us to the conclusion that criminal abortion is on the increase even in England.

Ricord is reported to have said that the best treatment of syphilis is the preventive treatment, and foremost in that he placed continence or the avoidance of infection. The same may be said of abortion. Dr. Rentoul has very clearly laid down the causes, and here preventive measures must take first place, so far as the avoidance of all the conditions which lead to the premature expulsion of the ovum or fœtus. Dr. Rentoul has an excellent chapter on the proper treatment of threatened abortion and all the states which may occur in connection therewith, and we must refer our readers to the book for fuller details. We can confidently recommend this essay.

Reports from the Laboratory of the Royal College of Physicians, Edinburgh. Edited by J. Batty Tuke, M.D., and G. Sims Woodhead, M.D. Vol. i. Edinburgh and London: Young J. Pentland. 1889.

This is the first volume of a series of reports which it is intended to publish from time to time, and which promises to be a valuable record of scientific research. It represents part of the work done in the laboratory of the Royal College of Physicians of Edinburgh during the first year of its existence, and contains eleven original articles on scientific questions related to medicine and surgery. One feature of the laboratory which, on reaching the report, strikes us at once as most commendable, is that it is available for use by individual members of the professsion who can by means of it subject their pathological specimens to a scientific examination, for which they seldom have the needful appliances at their disposal. The notes on the equipment of the laboratory, by Dr. Woodhead, describe a variety of ingenious contrivances which show the care and attention to minute detail expended, but which are of direct interest to those only who are actively engaged in experimental research. Of more immediate concern to the practical surgeon is the article on the use of mercuric salts in solution, as antiseptic lotions, by the same author. It is here shown that corrosive sublimate dissolved in water is by no means the perfect antiseptic it has lately been adjudged to be; inasmuch as its intensely poisonous properties render it dangerous for general use; and in contact with proteids it forms insoluble albuminates which have no antiseptic value. The latter objection is in practice overcome by adding to the solution an excess of tartaric acid which prevents the formation of the albuminate; but this proceeding accentuates the former objection since the mercury being kept in solution resists the action of all the ordinary antidotes. Instead of a solution of the perchloride, Dr. Woodhead recommends a solution of the biniodide formed by the help of a slight excess of iodide of potassium. This solution, while less poisonous than that of the perchloride, is thoroughly reliable as an antiseptic, as the biniodide does not combine with proteids to form albuminates. It has the further advantage of not affecting instruments immersed in it. Dr. D. B. Hart's researches on the mechanism of the separation of the placenta and membranes during labour are chiefly of scientific interest. His paper is carefully worked out, and presents the subject in a new light. It is sad that valuable writing of this kind should be disfigured by an etymological blunder that a mere tyro at a public school ought to avoid. The writer repeatedly uses the word *deciduæ* as the plural of *decidua*, as if the latter were a noun of the first

declension, whereas *decidua* is itself the neuter plural of the adjective *deciduus*. We have heard the form *scybalæ* used in a similar way, in contravention of the fact that *scybala* is a neuter plural (from σκύβαλον). Such barbarisms should have no place in the literature of a learned profession. Dr. Bruce has carefully described a brain affected with congenital absence of the corpus callosum, and has added a collation of recorded cases in which a similar defect existed. Besides the light thrown by this case on the development of the brain, it is of value in connection with Professor Hamilton's view that the internal capsule is mainly composed of callosal fibres. If Professor Hamilton's view is correct, we should expect that where the corpus callosum is absent, the capsule should be sensibly diminished in size; but in the present case it was normal both in form and extent.

We can recommend the Report on the Air of Coal Mines, by Dr. Nasmyth, to all who are concerned with mining. The volume is embellished with numerous excellent plates, many of them coloured to represent alterations of tint.

T. R. Bradshaw, M.D.

The Causation of Diseases. By Harry Campbell, M.D., B. Sc. (Lond.). London: H. K. Lewis, 1889.

The object of this book is to trace out the ultimate causes of disease—not of particular diseases—but of diseases in general. We shall best demonstrate its aims and methods by giving a quotation or two:—"Having inquired into the causation of S. and E. separately, it now becomes necessary to consider these two vital factors in the mutual interaction of disease, for we have seen that disease is an abnormal interaction of S. (Structure) and E. (environment). It will be remembered that we first inquired into the nature of E., and that the last chapters were devoted to the consideration of the causation of S.; we found that S. was mainly the outcome of heredity, but that it was also influenced, though in a lesser degree, by E. Accordingly, we treated of the causation of S. under two heads. Under the one we considered the general principle of heredity; and under the other the influence of E. upon S. So that E. has had to be treated of in a two-fold manner. 1. As one of the two great vital factors. 2. As a plastic agent. We now cease to study the two great factors of disease apart, and proceed to consider their morbid inter-action remedy—disease." "Now can we in any way symbolize the relative share taken by S. and E. in the causation of disease? Let us suppose a given disease to be made up of eleven units, and let the share in causation taken by S. and E., respectively, be represented by any number from one to ten; it would be manifestly incorrect to assign the full number (eleven) to either, seeing that neither S. nor E. alone can constitute disease. Then, inasmuch as S + E = the disease, we may arrange the following table:—

* *a.* $S_{10}+E_1=11$
b. $S_9+E_2=11$
c. $S_8+E_3=11$
d. $S_7+E_4=11$
e. $S_6+E_5=11$
f. $S_5+E_6=11$
g. $S_4+E_7=11$
h. $S_3+E_8=11$
i. $S_2+E_9=11$
j. $S_1+E_{10}=11$
† *k.* $S_0+E_{10}=10$

* An individual in whom the disease burst out spontaneously.

† An individual in whom the largest quantity of specific pathogenisis is unable to induce the disease."

Further elaboration of, and various illustrations of the numerical expression of our thoughts are given throughout the book, and are intended to give those thoughts a precision which they otherwise lack. For instance:—"It may happen that neuralgia of the fifth nerve disappears after withdrawal of the offending tooth, in which case the causation may have been summed up as follows:—$S_6+E_5=11$. By removing the five units of causation we cure the disease. On the other hand, the neuralgia may continue unabated after the tooth has been withdrawn, when the causation would be thus represented:—$S_{11}+E_0=11$. Just such a case, however, may not unfrequently be cured by diminishing the pathogenic value of S. Supposing, for instance, the causation to be more or less accurately represented by the formula S_6+E_5, it will follow that, if by tonics and rest we can reduce the S_6 to S_1, the patient will be cured."

The above quotation will serve to show the methods adopted by the author. Whether the plan does serve to give precision may be open to question, and will be judged of differently by different minds. Those who revel in Spencerian metaphysics will be delighted with the way in which the subject has been worked out; the mathematical mind will also revel in the formulæ and symbols adopted; to many the problems of disease do not render themselves amenable to the jugglery of the metaphysician or to the accuracy of the mathematician, and to them the book will not be an attractive one. Those who read it carefully will find much well thought out food for reflection, as many of the most interesting problems bearing on the evolution of disease are discussed in detail, and surveyed from a comparatively novel standpoint. The last paragraph in the book is one which will tempt the reader to buy the volume and peruse it in detail:—"I am led, on *a priori* grounds, to conclude that malignant disease is due to peculiarity of both S. and E.—peculiarity of S. as already set forth, and peculiarity of E in the shape of a specific parasite."

R. Shingleton Smith.

Notes on Venereal Diseases. By H. de Meric, Surgeon to the French Hospital, London. London: Renshaw, 1889.

This book, the outcome of much experience, deals with the clinical questions associated with syphilis, and its treatment, and lays down very clearly the points of distinction between the two kinds of venereal sores—that which is, and that which is not, syphilitic. He says (p. 13): "I am sure it must have been a source of wonder to others, as well as to myself, that hospital patients do not often reproduce in their lips and in their noses, through the medium of their fingers, the simple sores existing in the penis. On the other hand what a slight contact will communicate syphilis from one person to another—kissing, drinking out of the same vessels, etc. This difference is still more clearly demonstrated by the germ theory, if we regard simple sores as merely the result of putrefactive inflammation, and syphilis to be caused by the absorption into the system through the syphilitic chancre of a definite bacillus." In considering the question of treatment, he asks, "How does mercury act in the disease?" His reply is as follows:—"Not only as a remedy, but almost as an antidote, by destroying the bacilli of syphilis. At the present time this assertion is mainly based on theory, but I think we may go still further and consider, or at least hope, that the period is not far distant when the duration of the specific treatment (*i.e.* the

administration of mercury) will be determined by the disappearance of the syphilitic bacillus from the patient's blood." A page or two further on he remarks that "it seems a sort of hard-and-fast rule that the treatment of primaries should be mercury, combined even sometimes with iodide of potassium; that of secondaries, the two drugs united; and that of tertiaries, iodide of potassium alone. This routine, though in the main based on sound clinical observation, must not be allowed to altogether influence the surgeon. He must always bear in mind that mercury is his sheet-anchor, whilst the iodide of potassium is but an adjunct." The book is a condensed epitome of clinical experience, not burdened by any abstract disquisitions or theoretical questions; it is well worthy of perusal by those who have to treat any of the varieties of venereal disease, either local or general.

R. Shingleton Smith.

The Diagnosis and Treatment of Extra-Uterine Pregnancy. By John Strahan, M.D., M.Ch., etc. (Jenk's Prize Essay of the College of Physicians of Philadelphia). Philadelphia: P. Blakiston, Son and Co.

In this essay of 125 pages Mr. Lawson Tait's name occurs over eighty times, so that it is not too much to say—looking at the references in the essay—that it could never have been written had not Mr. Tait previously also written. The following sentences in the book are remarkable:

1. "Lawson Tait has *perhaps* more experience of such cases than any man living, and more than any man who ever lived. The writer is inclined to agree with most of Tait's views on pathology, although Tait is evidently too dogmatic on several points in diagnosis and treatment" (p. 1).

2. "Although I have a very great respect for every opinion of Mr. Tait upon a subject he has made peculiarly his own, yet I do not slavishly follow whatever he may say, unless it is well supported either by himself (*sic*) or others" (p. 24).

3. "Tait is doubtless too confident in his own unique experience, and too sceptical as to the assertions of others. We must remember that after all he has *only* seen seventy-nine cases (published up to date of his new book, December 1st, 1888), and this number is far too small to permit of any dogmatism as to what can and what cannot happen in other cases. There can be no doubt, however, that he is right as refers to the overwhelming majority of cases, and we may safely accept his last opinion on the matter—viz., 'One might guess, but it is impossible to affirm; for one case we could diagnose, fifty would escape recognition'" (p. 24).

In reference to the first sentence, the word *perhaps* should be omitted, and then the sentence would be correct. The author confesses that he is disposed to agree with Lawson Tait's views of pathology. What other views could he support? We fail to find out in the book any evidence to show that Tait is too dogmatic, either as to diagnosis or treatment. The second sentence is a contradiction in terms, and the third may be classed in the same category. Both sentences illustrate what is seen through the work—viz., a disposition to use qualifying adjectives, or, in other words, to "hedge." He does not, save with a few exceptions, make clear his own opinions upon knotty points on which we really want light. This is particularly seen in the section "On Treatment of Extra-Uterine Pregnancy before Rupture, should a Diagnosis be made" (p. 72), where a considerable amount of doubling is gone through; and after pages of quotations, he comes to the conclusion which Lawson Tait had already laid down. In this section we have one of his disagreements with Mr. Lawson Tait. Mr. Tait, as we know, objects to killing the fœtus on many grounds, one being that it is immoral. This is is how Dr. Strahan treats this objection: "I will not waste words on the objection that killing the fœtus is immoral, as in the stage, of which we are considering the treatment, the chances of life for the fœtus are so poor that they cannot be much worse. The great majority die at rupture (with the mother, or by the operation to save her life). . . . I certainly do not see the immorality of killing the ovum before rupture." Mr. Tait, with his exceptional experience, clings to the old-fashioned law, "Thou shalt do no murder," and apart from all the other questions which underlie the subject of killing the fœtus, as the growth of the placenta, the dangers, etc., the right of the fœtus to a chance of life appears to us to be based upon justice. This may be a matter of opinion, but the terrible case of killing reported by Dr. Matthew Duncan should convey a very plain and salutary lesson. We must, however, leave controversial matter, and give our readers an outline of the book, as this subject is coming to the front, and a *precis* of our existing knowledge of extra-uterine pregnancy must be useful to every practitioner. To fully understand the subject, Lawson Tait's lectures "On Ectopic Pregnancy" should be read in full; then this compilation may be consulted. Dr. Strahan's essay is divided into two parts. Part I. gives the history and pathology of the condition, diagnosis, diagnosis previous to rupture, diagnosis from normal gestation, conclusions as to the diagnosis up to the period of primary rupture (during first three months), normal pregnancy mistaken for extra-uterine pregnancy, is the diagnosis of the variety possible before rupture? diagnosis at the time of and shortly after rupture, diagnosis after the shock of primary rupture is over, diagnosis about the viable period, diagnosis after full period of gestation and fœtal death, diagnosis of suppuration in an extra-uterine gestation sac, differential diagnosis, summary of the diagnosis. The second part is devoted to treatment, and is divided into the following sections: Treatment of early extra-uterine pregnancy, and when rupture occurs, treatment before rupture should a diagnosis be made; methods which have been recommended for bringing the pregnancy to an end, even in the pre-ruptured stage; treatment at period of primary rupture; resuscitation of patient after rupture; the operation for tubal gestation; treatment between primary or tubal rupture and the full period of gestation; treatment at the full period; the primary operation; vaginal extraction of the child. Dr. Strahan has evidently examined carefully the literature of the subject, and has brought together from the contemporary literature of England, America, France, Germany, the leading facts and theories on extra-uterine gestation. It lacks one essential—viz., individual experience, which detracts very considerably from the value of the author's own opinions.

Lectures on Bright's Disease. By Robert Saundby, M.D., etc. Fifty illustrations. Bristol: John Wright and Co.

The object of this book is not only to present within a modest compass the present state of knowledge on Bright's disease, but to give the author's views, as formed after

thirteen years' clinical and pathological study of the malady. Dr. Saundby has published many separate papers, in which he has given us sketches and suggestions; but in this book he has, as it were, crystallised all his work, and it may be taken as representing his more matured opinions. The book is divided into three sections:

Section I. deals with general pathology, and consists of seven chapters—albuminuria, pathology of dropsy, pathological relations of tube casts, cardio-vascular changes, pathology of polyuria, pathology of uræmia, retinal changes. All these conditions are clearly, but concisely described, illustrations being introduced where necessary to clear up the text, whilst at the end of each chapter is an excellent bibliography.

Section II. deals with the clinical examination of the urine, and opens with the following but too true paragraph: "Inspection of the urine is an ancient medical practice, which, for the most part, was until recent times a meaningless and perfunctory medical ceremony." Dr. Saundby would lift urine testing into a higher level, and his description will come as a revelation to those who have been content to carry on urine testing in a routine fashion.

Section III. deals with Bright's disease under the following headings: history, classification, etiology, general anatomy of the kidney, febrile nephritis, lithæmic nephritis, complications of chronic Bright's disease, treatment of lithæmic nephritis, concluding with an excellent general index. There is an excellent bibliography to all these chapters, and as Dr. Saundby is an accomplished German scholar, German literature is largely represented in this. The treatment of lithæmic nephritis is laid down as follows at chapter xv.: "We are all liable to try to do too much in the way of treatment," he says. "... If a patient suffering from chronic Bright's disease is in fair general health, and the discovery of the lesion has been made more by accident, so to speak, we should be careful to do nothing that would *worsen* his condition by over-vigorous treatment or too severe regimen, but should be content to relieve the symptoms of which he complains, if it is in our power to do so; while, at the same time, we endeavour to regulate his habits and mode of life in conformity with principles deduced from our knowledge of the etiology and pathology of his disease."

What these measures are the author then tells us in detail. Climate and hygiene, clothing, exercise, hot air and vapour baths, diet, are fully considered. Thus a dry, warm climate is recommended for the winter. The patient should wear woollen clothing day and night, summer and winter, in all climates. Hot air or vapour bath once a week at home; daily exercise should be encouraged, but violent exercise avoided; abstinence from butchers' meat, cheese, and all alcoholic drinks should be enjoined. Dr. Saundly enters into full details as to choice of residence, tell us what the patient should have for diet, etc. As a general prescription to fulfil the main indications of those cases where no special symptoms are calling for treatment, or contraindicate its use, a mixture containing sodium benzoate, and digitalis, may be employed.

℞ Sodii benzoatis ..... gr. x.
Tincture Digitalis ..... ♏ x.
Inf. gentianæ ad. .... ℥ j.
Sig. To be taken three times a day.

The bowels should be kept open by some laxative if they are at all sluggish.

℞ Euonymini ..... gr. j.
Ext. Aloes ..... gr. ij.
Ext. Belladonnæ ..... gr. ¼.
f. t. pil.
Sig. To be taken at bed time when required.

This is the general treatment, and we would refer our readers to the work itself for fuller details, which we cannot give in a review.

There are few diseases upon which the general practitioner is more frequently consulted than Bright's. Its recognition in the early stages is all-important. During late years, immense strides have been made in regard to diagnosis, pathology, and treatment; hence the value of a work of this nature, which gives, within a reasonable compass, all that is best in modern literature, supported at the same time by individual practical experience, so that it is a work which the conscientious general practitioner ought to have by him. We must congratulate the publishers on the excellent way the book has been produced.

Short Notices.

Tooth Extraction: a manual on the proper mode of extracting Teeth. By JOHN GORHAM, M.R.C.S.

THAT we have here a third edition of this manual, within a period of two years, is *primâ facie* evidence of its utility. It appears to be addressed principally to medical practitioners, a class of readers who have obviously found their account in the study of its pages. Dental surgery is a department which few of us have the opportunity of culti vating before we are called upon to "draw" teeth. All who may find themselves thus placed will find serviceable instruction and counsel in this little work. The names and arrangement of the teeth, at the several periods of life, are given in tabular forms. The instruments best adapted for extraction are described, together with special directions for the extraction of each tooth. The short section on anæsthetics in dentistry contains very judicious counsel in short space. W. B. KESTEVEN, M.D.

Deviations of the Nasal Septum. By GEORGE STOKER, M.D. pp. 24. 8vo. London, 1888.

THE deviations here dealt with are deflections, spurs, enchondroses, and exostoses. The conditions to be relieved are: "1. Obstruction to the free passage of air through the nose. 2. Extreme lateral displacement, due, as a rule, to accident, and causing great disfigurement. 3. Where some deviation which, though not actually obstructing the passage of air, causes catarrh or some reflex symptom." These deviations, Dr. Stoker points out, are not always externally evident, but may require a careful internal examination. For this purpose, a properly contrived speculum has been made, and is here described, together with instructions for its use.

Other instruments, which are also frequently required, are explained and illustrated by engravings. The various operative measures that may be called for are also fully described by Dr. Stoker. W. B. Kesteven, M.D.

On the Futility of Experiments with Drugs on Animals. By Edward Berdoe, L.R.C.P., etc. pp. 46 London, 1889.

This pamphlet is published under the auspices of the Society for the Protection of Animals from Vivisection. It consists of a review of the "Report" and "Returns," showing the number of experiments performed upon living animals during the year 1887, under licences granted under Act of Parliament. "These have been made, in the case of new drugs, either with the view of justifying the further extension of such remedies to man, or of enlarging their sphere of usefulness; in the case of some of the old drugs, with the view of inquiring whether their action is such as to justify their continued administration for the purpose for which they have hitherto been used. The experiments consisted chiefly of hypodermic injections, and were mostly of a painless character. . . . . Whether the latter statement is fact or not will be shown in the course of inquiry." . . . "The method adopted in these pages" by Dr. Berdoe "is to take the principal drugs and chemicals which are used in the practice of medicine, and compare and contrast their action on the different species of animals upon which they have been tried, both with each other and upon man." To this end the whole materia medica, in which these actions are most clearly shown, is laid under contribution with references to and explanations of their different actions as laid down by experimenters, British and foreign. The conclusion arrived at by the author may be anticipated from the title of the pamphlet and the auspices under which it is put forth. We would, however, take leave to quote the words of Sir Lyon Playfair, in his speech in the House of Commons on Mr. Reid's "Bill for the Total Suppression of Scientific Experiments upon Animals," as deserving of Dr. Berdoe's serious consideration: "The justification is that man's duty to man is greater than man's duty to beasts."

W. B. Kesteven, M.D.

Cremation and Urn Burial; or the Cemeteries of the Future. By W. Robinson. London, Paris, New York, and Melbourne: Cassell and Company.

In this profusely illustrated *brochure* Mr. Robinson points out the advantages that would result from the universal adoption of cremation. It is an exhaustive treatise on this subject. The general objections to the system are fairly discussed. The rules adopted by the English Cremation Society are well devised. The work is well printed, and the illustrations are exceedingly good.

Elementary Bandaging and Surgical Dressing, with Directions concerning the Immediate Treatment of Cases of Emergency. By Walter Pye, F.R.C.S. Third edition, revised and enlarged. pp. 208, small 8vo. 1889.

It must be assumed that this treatise has been found to have attained its purpose, which is to instruct dressers and nurses in the management of accidental injuries, and other cases of emergency. Within the short period of three years it has reached a third edition. We would venture to express our concurrence in this professional verdict. The directions throughout are concise, clear, and judicious; the illustrations precise, definite, perspicuous. Every surgical student, dresser, or nurse should have a copy of this little book at hand, or in the pocket.

W. B. Kesteven, M.D.

The Harveian Oration, 1888. By P. W. Latham, M.A., M.D. Cambridge, 1888.

This oration might be entitled the influence and mode of action of the pathogenic micro-organisms, and the author endeavours to shew that the pathological changes are produced by ptomaines quite independently of any bacterial action. R. Shingleton Smith.

Papers on Dermatology. By E. D. Mapother, M.D. London: Churchill, 1889.

This volume of a hundred pages consists of a series of papers on a variety of topics. Some of them more than skin deep. One of the most important, on the correlations of eczema and gout, strives to show that constitutional eczema depends on the gouty diathesis, and therefore should be treated according to the well-known therapeutic indications observed in that condition. A paper on the treatment of the syphilides is well worthy of perusal, but contains nothing new. The last essay gives an account of two little known Irish Sulphur Spas, Lisdoonvarna and Lucan. R. Shingleton Smith.

Pathological Report, 1887-1888, *of the City of London Hospital for Diseases of the Chest, Victoria Park, London, E.* By Sidney Martin, M.D. (Lond.), Assistant Physician to the Hospital, late Pathologist and Medical Registrar. Glasgow: printed for the Victoria Park Hospital, by James Maclehose and Sons, Glasgow, 1889. Folio pp. 33.

The diseases of which cases are here tabulated include phthisis, empyema, bronchitis, kidney disease, aneurism, Addison's disease, pneumonia, new growths, and cardiac disease. The cases of each of these have been arranged in tabular form, noting the several heads of age, duration of disease, heredity, complications, time of death, condition of the internal organs, with sundry other items, and a summary with remarks.

The Provincial Medical Journal,

JULY, 1889.

IN the Report of the Commission on Hydrophobia occurs the following paragraph: "The annual number of deaths from hydrophobia, during the ten years ending 1885, was, in all England, forty-three; in London, 8.5. If, as in the estimates used for judging the utility of that method (PASTEUR'S) of treatment, these numbers are taken as representing only five per cent. of the persons bitten, the preventive treatment will be required (yearly?) for **860** persons in all England, for **170** in London alone. For it will not be possible to say which among the whole number bitten are not in danger of hydrophobia, and *the method of prevention by cautery, excision*, are not to be depended on." This is one of the most extraordinary paragraphs in this very extraordinary report, and reveals such a want of acquaintance with the past statistics on the relation of dog-bites to hydrophobia, that we are astounded how it ever could have been introduced into a scientific report. But let that pass, and let us see how many have actually gone from England to PASTEUR. We have M. PASTEUR'S authority for the number. In a letter to the Lord Mayor of London, he tells "that we have had under our care **88** of your countrymen in 1886; **24** (?) in 1887; **63** in 1888; and already **35** in in the first five months of 1889; making a total of **210**, or an average of **50** for each year."

Compare the actual number who have gone with the estimated average, and then compare the mortality of the different years, and M. PASTEUR'S question will be answered. "It is probable (M. PASTEUR might have said certain) that during the last four years there has been a large number of persons bitten by rabid animals in England, but that many of them, for various reasons, have not made the journey to Paris. It would be of great advantage to have a careful inquiry made into this matter, and to determine the rate of mortality amongst those who held aloof." We have some interesting statistics as to a number bitten by dogs in 1885, 1886, 1887, in the metropolitan area—bitten under nearly the same conditions as many of those who went to the Institute—viz., by wandering dogs. If we look at the list of those who went to Paris, we shall see such cases as that of Lord CRABTREE, etc., who were bitten by dogs which were simply savage or irritable; or that of the girl TATTERSALL, bitten by a wandering dog. In the statistics, the dog that bit TATTERSALL is said to "*be rabid*," *on authority of a veterinary surgeon;* in fact, the dog was not seen by a veterinary surgeon, as it ran away after biting the little girl, and was lost. During 1885, 1886, 1887, there were **286** policemen bitten by dogs of all kinds, rabid or not; **1,114** private persons, and **40** postmen. These figures represent a small tithe of the number that must have been bitten in England. In 1886 and 1887, there were two deaths from hydrophobia in the same area. The police must have killed a number of rabid dogs, and been bitten by rabid dogs. That is a probable and reasonable hypothesis. How many policemen have died in the metropolitan area? How many were sent to PASTEUR? How many thousands have been bitten in the provinces during the years 1885, 1886, 1887, 1888, by *suspicious* dogs? That only 210 should have gone over to Paris during the years is rather surprising. Of course, it means that only those who had money could afford the journey; in case of the poor, a subscription was raised. What has become of those who could not go, and who had to content themselves with cauterisation, etc.? They are none the worse for their imposed disability to join the fortunate few who were able to see the gay city by the Seine.

"*The methods of cauterisation, excision*, cannot be depended on" (Report of Commissioners). What saved the poor, who never have even heard of Paris, because the **50** out of the **800** is but a small proportion? If, in place of the concluding paragraph in the report, the Commissioners had had the courage of their opinions, and said "that a PASTEUR Institute was required in London," they would have been logical, and we could understand the report. But as it stands it is a movement of what is known in the racing world, as high-class or scientific "hedging."

Now, however, the proposed PASTEUR'S Institute is to be established, there is much writing up in the journals of the danger and frequency of rabies and hydrophobia, and M. PASTEUR has written to the Lord Mayor pointing out that there is a young scientist ready trained, and England should redeem her character. We have not one word to say against a PASTEUR Institute in London. We do not think it is required, but those who believe in the system are perfectly justified in carrying their convictions to a logical conclusion. We should naturally prefer to see common sense triumphant, to see rabies stamped out as it has been stamped out in Germany, by intelligent direction of police laws, so that hydrophobia should be unknown, but with the visit of the Lord Mayor of London to Paris it became inevitable that we should soon have a PASTEUR Institute in London; the reign of common sense is always at an end when fashion comes in, and takes the reins. VINCENT RICHARDS, in India, has ably pointed out the fallacies underlying the statistics, and we agree with his latest utterances.

"But whatever the uncertainties of these French cases may be, the certainties of the English ones are pretty clear as gathered from the Parliamentary returns, cited by the *Lancet*, showing that of the twenty-four persons treated for bites, said to be unquestionably rabid, three died. An unsuccessful result, which, says the *Lancet*, 'must probably be attributed to the inoculations being performed too late'—presumably after infection had taken place; but it is not thought necessary to enlighten us as to the number of days that had elapsed between the reception of the bites and the commencement of the treatment, or as to why absolute success for the method is claimed in those cases, in which sufficiently long intervals had occurred to permit of infection, had the patients been inoculated with rabic virus before

they came under Pasteurization. I must, therefore, beg to differ with the *Lancet* when the editors assert that in spite of adverse criticism the treatment has been found to be efficacious. On the contrary, every one of the proofs advanced in support of the ever-shifting methods has crumbled to pieces under close and intelligent examination. Ought M. Pasteur to be surprised at the opposition he has met with? Has his mode of procedure been such as to court confidence? Has he not, from time to time, before the exposition, modified his method and treatment, until at last we find the method, which was declared perfect as a cure, is admittedly useless *when infection has occurred.* After such an admission as that it is clearly ridiculous for M. Pasteur or M. Grancher to claim success by a statistical manipulation of figures which are based upon an assumption radically and totally opposed to its terms."

At a meeting of the College of Physicians, Philadelphia, on May 1st, Dr. J. P. Crozer Griffith read a very useful paper on the unpleasant effects of sulphonal; and in view of the many articles written in praise of this product, Dr. Griffith's experiences should be borne in mind. Dr. Griffith states that he does not desire to decry a useful medicine, but to aid in establishing its true value in comparison with other hypnotics. The cases he refers to in his paper occurred in his own experience. The following are some of the chief disadvantages of the drug:—

1. *Its slowness of action.*—So generally, indeed, says Dr. Griffith, has the experience of clinicians agreed on this point, that Kast, who first employed the drug, has written a second article which might almost be called *a defence* of sulphonal, and in which he discusses the reasons for this long delay in action.

2. A greater difficulty to be overcome in the use of sulphonal is the marked tendency which its hypnotic action has to persist during the following day. Dr. Griffith gives cases in support of this. This prolonged hypnotic action has frequently been referred to by writers. L. L. Johnson (*Medical News*, September 8th, 1888), for example, reports a case in which the patient promptly fell asleep after thirty grains of sulphonal given in the evening, but was very somnolent until afternoon of the next day. In smaller amount the drug acted very well. Algeri (*La Reforma Medica*, No. 233, 1888,) says that the action of large doses continues through the following day, and Oestreicher (*Berlin klin. Wochenschr.*, June 18th, 1888,) has seen sleep absent during the night, but persist through the following morning. Lovegrove (*Brit. Med. Jour.*, May 26th, 1888), too, states that the effects on patients to whom he gave the drug were very discouraging. For several hours after taking it no appreciable action could be noticed, but during a great part of the next day there was extreme drowsiness and considerable cyanosis. The case of Schotten's is of especial interest in this connection. Kast discusses this "postponed action" in the article referred to, admitting that it is often witnessed, and that it constitutes a great disadvantage when it is necessary that the patient be actively employed during the day. For this difficulty he has no special remedy to propose in addition to the method of administration described, except that the dose be carefully adapted to the individual.

3. But this *determination of the individual dose*, in order to overcome the difficulties mentioned, itself constitutes a sometimes insurmountable obstacle to the use of sulphonal. The amount necessary to produce satisfactory sleep was followed by the prolonged effect on the following day, or by various unpleasant after-effects presently to be described, while any smaller amount failed to bring the desired result during the night. In quite a number of cases it was observed that a small dose merely served to render the patient uncomfortable in the night and upon the following day, while a full dose procured satisfying sleep, and the morning was free of prolonged action or disagreeable after-effects. It would seem sometimes as though sound sleep were necessary to exhaust, so to speak, the action of the medicine. Matthes (*Contralbl. f. klin. Med.*, No. 40, 1888; *Wien. med. Blätter*, December 13th, 1888), too, reports a case in which very marked disagreeable after-effects appeared to develop because the sulphonal-sleep had been much disturbed by outside causes.

4. *Unpleasant secondary effects.*—Many writers have observed them, so that the claim made by the makers of the drug and by some of its users, that it is totally without disagreeable secondary action, is not substantiated. A tendency to an excited mental condition *accompanying* but not *replacing* sleep is shown by cases III. and IV., but especially by X. Temporary *delusions* after the ingestion of the drug are reported by Furbringer (quoted by Zerner, *loc. cit.*), and may be classified in the same category with the excited mental conditions I have reported. *Nausea*, *dizziness* and *headache* have been already mentioned as effects which may follow the ingestion of sulphonal. Rabbas (*Berlin. klin. Wochenschr.*, April 23rd, 1888), has been vomiting on the morning after the ingestion of sulphonal, and in another patient *diarrhœa* occurred; but he is not certain that these symptoms were attributable to the action of the medicament. *Heaviness in the head* and dizziness were observed by Sachs (*New York Medical Record*, October 6th, 1888), in a patient who had taken two doses each of 2 grammes three hours apart. Schwalbe (*Deut. med. Wochenschr.*, June 21st, 1888) has in several instances observed dizziness, headache, nausea, and in one case vomiting, after a dose of only 1 to 1.5 grammes and S. G. Burnett (*New York Medical Journal*, March 2nd, 1889) has seen two instances of vomiting. The production of a marked *sense of fatigue*, of *depression*, and of *confusion of mind* is not infrequently referred to by authors. J. Frankel (*Berlin klin. Wochenschr.*, July 23rd, 1888) has found these symptoms so decided in a number of patients that the drug could no longer be given them; Matthes (*loc. cit.*) refers to the sense of exhaustion and depression as the secondary effects most frequently observed, and Oestreicher (*loc. cit.*)

has seen them in one or two out of eighteen cases. In one of these it was very pronounced, and the patient refused to take the medicine again. OTT (*Prag med. Wochenschr.*, October 3rd, 1888) refers to the sense of fatigue on waking as the chief bad symptom which the drug leaves behind it. He reports a case in which three grammes caused vomiting and an attack of *fainting*. The confusion of mind is exemplified in several of the cases I have reported, especially in case XII. In two instances I have seen full doses of sulphonal produce a *disturbance of gait.*

The occurrence of a drunken staggering gait has also been reported by ZERNER and by OTTO-DALLDORF.

ENGELMANN details a case in which three grammes produced an erythematous eruption over the breast and inner surface of the arms, attended by considerable itching. Another instance of an eruption occurred in a case of SCHOTTEN'S. SCHMEY details most unpleasant results following the administration of sulphonal to a case of angina pectoris from arterio sclerosis.

5. Finally, the *uncertainty of hypnotic action* is one of sulphonal's disadvantages—a fault which it shares with all hypnotics. Cases of failure of action on the part of sulphonal are too numerous in the literature to allow of quoting from them. Among those who have been unfavourably impressed by the drug, on the ground of its inefficiency, may be mentioned WILSON and HUTCHINSON (*Med. and Surg. Reporter*, June 9th, 1888), LOVEGROVE (*loc. cit.*), SALGO (*Wien. med. Wochenschr.*, No. 22, 1888), and REGIS (*Journ. de Méd. de Bordeaux*, July 1st, 1888). The views of Dr. GRIFFITH must be taken into account by those who intend to try sulphonal; thereby disappointment will be spared by knowing beforehand that there are some drawbacks, and that certain symptoms may follow its use.

THE French journals are very fond of *feuilletons*, or *causeries*, bearing indirectly on medicine. These pleasant chatty papers are written for medical men who like to vary the monotony of pure professional details by reading light articles, by which their minds are unbent, as good old ÆSOP suggested in one of his fables. In the *Journal de Medicine de Paris*, June 8th, 1889, there is a very interesting *feuilleton*, showing the influence exercised by the study of medicine on a number of writers of eminence. "One always returns to one's first love;" and in the subsequent careers of eminent men we find, according to this writer, the influence of the first profession. SAINTE BEUVE was regularly entered—his first inscription dating 3rd November, 1823; the fifth, 13th November, 1827. In the autobiographical notice as sent to M. ALPHONSE LE ROY, professor at the University of Liége, published later by M. TROUBAT, he says: "He served for a year as *interne* at St. Louis," and that "he had benefitted much by the anatomical and physiological teaching he had received at that time." It now appears probable that he was an *interne* under RICHERAND, but he was not the sole master of the future author of *Causeries de Lundi.* There is reason to believe that anatomy occupied the attention of SAINTE BEUVE, for he was an anatomist all his life. His works remain to attest this. When he does not dissect his contemporaries he dissects himself. Impitiable, he acts as the anatomist, dissecting everything, examining everything, analysing everything.

BALZAC says, in his "Physiology of Marriage," that "One should not marry without studying anatomy and at least dissecting a woman." For the purpose of the critic the dissection of a man would serve as useful a purpose, and this training which SAINTE BEUVE received may account for his skill in his psychological dissections.

Another critic, whose works reveal that he has held the scalpel, is TAINE, whose precision, though differing from that of SAINTE BEUVE, reveals the hand of the master.

RALISBONNE calls TAINE an *anatomist à outrance.* Prince NAPOLEON calls him better an entomologist. "Nature created him to classify and describe strange collections. He is a perpetual analyst, always armed with his section forceps, and taking a pleasure in dissecting his victim up to the last fibre. If he examines a philosophy he wants to know the medical bulletin of the life of the philosopher; if he examines a work of art, the pathological state of the sculptor or the painter." We cannot say much of the charming poet to whom the beretomaniacs desire to erect a statue—a tardy homage, which will not add anything to his glory—ALFRED DE MUSSY, who sings so charmingly of our joys and sorrows. In 1827, at the instance of his father, he entered the study of medicine, and followed the course of M. BALLARD, the physiologist. The study of medicine did not suit him, and we need not regret that he exchanged the bistoury for the pen. Next is mentioned the poet JEAN RICHEPIN, the poet LOUIS BOUILBET, and two paladins of the press. At the present day JULES CORNELY, whose pen is as keen as the blade of a surgical instrument, is in the foremost ranks of journalism. He commenced his medical studies at Lyons, and was *interne.* When he gave up medicine and started for Paris all his baggage consisted of a drama. Then the writer briefly alludes to ADRIAN MARX, NARDOR, and CHARLES CROS.

LITTRE, who knew everything, and knew it well, was an *interne*, but did not take out the doctorate; but he has left us his dictionary of medicine, a translation of HIPPOCRATES, and a book of medical varieties. In this gallery must be included the grand composer, BERLIOZ, who was a man of letters, as well as a musician. BERLIOZ' father was a practitioner, practising in the country, where he had a local reputation. The Medical Society of Montpellier in 1810 had honoured him for a memoir on chronic maladies. Six years later, in 1816, he published a treatise on acupuncture, then a series of observations on atmospheric conditions and their influence on the production of various pathological states. Dr. LOUIS BERLIOZ was the first master of his eminent son, for the father did not foresee the distinguished career of his pupil. Young BERLIOZ was restive under the paternal yoke, and did not take kindly—even with the

temptation of a magnificent flute—to the study of the osteology of Munro, a beautiful copy of which his father had. At the age of sixteen young Berlioz went to Paris, and entered the Faculty, attending the course of Gay-Lussac on experimental electricity, of Thenard on chemistry, and Andrieux on literature. He assisted with a stoical resignation at the course of anatomy of Professor Amussat, but medicine did not attract him: music held him in her chains. He says: "To be a physician, to study anatomy, to dissect, to assist at horrible operations, in place of giving myself body and soul to music, that sublime art, the grandeur of which I already conceived; to quit the empyrean for the more sad region of the earth, the immortal angels of poetry and love and their inspired chants for dirty muses, frightful *garcons* of the amphitheatre, hideous corpses, cries of patients, moanings, and the *râles*, the precursor of death. Oh, no! all this seemed to me the absolute reversal of the order of my life, monstrous and impossible." His dislike to medicine became stronger when he was taken for the first time to the dissection room of La Pitie. He has left us a realistic description: "The aspect of this horrible human charnel house," he cries in his *Memoires*, "the dishevelled members, the grimacing heads, the opened crania, the bloody choaca, the revolting odour exhaled, the swarms of sparrows disputing for shreds of lungs, the rats gnawing in their corners the bleeding vertebræ, filled me with such horror that, jumping through the window of the amphitheatre, I ran breathless home, as if death and his frightful *cortegé* were at my heels." Berlioz was decidedly a little poetic, and did not scruple at making the reader creep. No doubt, the dissection room in those days was not as spacious or as well managed as at the present day; but the rats and sparrows appear hyperbolical. A second attempt was not more successful; but events revealed his vocation—the opera. He went to hear Danaides, of Salieri; then farewell to the amphitheatre and the lectures of Amussat; and henceforth he devoted himself to the study of Gluck, and the numerous manuscripts of the library of the Conservatoire. Yet, though Berlioz's medical studies were short, we find that in his correspondence with Ferrand he quotes Hippocrates in Latin, which he no doubt learnt at the preparatory lessons of his father. In a letter to Schumann, he makes allusion to the methods of preparation of the anatomist's ruisch. His *feuilletons* are filled with medical terms, and his works bear traces of his scientific knowledge. In his "Musical Voyage in Germany" he quotes his old masters, Thenard and Gay-Lussac in his "Memoires." In his "Soireés de L'Orchestre," or in his "Grotesques de la Musique," he speaks of the noise which the blood produces in the head in passing through the carotid arteries, on the distinction of the cerebral lobes, on crucial incisions, etc. The principles of acoustics were familiar to him, and he criticises the theory of vibration, on which are founded the various systems of harmony. He observes and notes the resonance of the bells of St. Paul's, London, and then enters into a discussion on the hygiene of infancy *à propos* to the alimentation of poor children, to which he attributes a special influence in the development of the vocal organs. Dr. A. Cabanes, who has contributed this *feuilleton* to the *Journal de Medicine de Paris*, gives other instances of Berlioz, impressions caused by his first studies in medicine, and we think he has established his theme in his extremely interesting article.

The Mayor of Bath, Mr. H. W. Freeman, F.R.C.S., is to be congratulated on the success of the ceremony that took place in the ancient city on June 13th; nay more, the citizens of Bath owe him a debt of gratitude for the admirable manner in which he discharged his multifarious and responsible duties on that memorable occasion, whilst the guests are under an obligation to him for the courteous way in which he received them, and for the excellent arrangements he made for their enjoyment and comfort. In this he was no doubt loyally assisted by the Corporation, but we are fain to believe that the personal equation of the Mayor had a great deal to do with the system and order of the reception, and we feel sure that as a medical practitioner of eminence, he was able to bring from all parts of England his *confrères* to support him, in a way that no layman could have done. He can truly say when his term of office expires: "If you search for any proof of the work done during my Mayoralty, look at these magnificent baths, which your public spirit, under wise direction, has been the means of erecting." The ceremony of June 13th has a more than local importance—it is national. In the series of articles which have for some years been appearing in the "Provincial Medical Journal," we have been true to a few general principles, and we may again enumerate them.

First, there can be no wealth in life without health. Health means not only happiness, but as we shall see material prosperity. To purchase health, men will give all they possess; they fly from country to country in search of the means of restoring it; and it is as true to-day as it was some thousand years ago, that "a man will give his skin for his life." Health-giving waters abound in England. It it a national duty to preserve and develop them. We must grant, that whilst we can, as a rule, give patients absolute relief in sickness, yet we cannot, in many cases, complete our work without bringing to our aid change—change in diet, air, surroundings—and this change can be best secured at a sea-side resort, or inland spa. These elementary ideas we have frequently dwelt on, they may seem puerile, but elementary principles are open to this objection. Now, corporations or authorities which possess arsenical, saline, chalybeate, and bromine waters in their localities, should consider that they hold them in trust for the nation, for here in this England of ours we should be able to utilise all our national resources in whatever way we possess them, and not the least in value are our mineral springs. This is the first and the highest aspect of the question, that the restoration to health of our people should be possible of achievement here in England, *eito tuto et jucunde;* and that

it should be within the reach of all to use chalybeate and other waters; that riches and rank should not alone monopolise them; and that, in the interests of the whole nation, each mineral spring should be fully utilised, arrangements being made that the application of the waters should be made under the best conditions, not only of hygiene but of commerce.

Second, we have said that mineral waters must be classed amongst our national commercial resources, just as much as coal, tin, iron, or even gold. On the continent, this principle has been fully realised. A mineral spring may be made as remunerative as a lead, iron, or tin mine. It may bring to the locality thousands and thousands of visitors, who will distribute wealth to the community, so that towns virtually live out of the visitors who come to seek health. At continental watering places and spas the industrial aspects have been so fully considered, that every attraction is set forth to induce visitors to come. The syndicates, which own the waters, or the corporations, invest large sums of money in costly buildings, such as casinos, kursaals baths. Excellent bands are engaged, so that, whilst the persons are taking the waters, promenading in the open air becomes a pleasant pastime. We need not point out how much the amusements, the bands, the concerts, add to the attractions of any "cure," or the absolute importance of the installation of baths. This is also elementary, but we are here in England only beginning to appreciate these facts. We have too long allowed the foreign health resorts undisputed opposition. We have almost compelled English patients to go abroad. Though we do not expect to do away with resort to foreign watering places, nor do we deem it absolutely desirable, yet we may, by opening such baths as the ones just installed at Bath, induce English patients to spend their money in England, and to give support to what is British industry. This is not Chauvinism—it is patriotism of a proper kind. If at Bath we have mineral waters equal to those of the Continent; if health can be purchased by resorting to them; if the advantages to be obtained are as great, if the baths and the surroundings are equal, it does not require much exercise of reason to arrive at the conclusion that the patient who overlooks all these points, and who still desires to go abroad, is acting without much sense. The profession in England, we feel sure, will respond to the invitation of the Mayor to make known to their patients the advantages of Bath as a health resort; and now that the bathing arrangements are as complete as at any foreign watering place, they can do so without any fear of being reproached for their advocacy.

The economic aspects are well worth the consideration of patients. Sickness is expensive; resources even of well-to-do families are much crippled by chronic disease; the expenses of a continental journey and residence are very high, apart from the long distances to travel, the inconveniences of foreign lodging houses, the diet, the difference in language, so that when we place in the scales the reasons for home residence and those for foreign residence, the balance in favour of the former kicks the beam. We trust that the new baths will fully realize all that is hoped for them, and that the Mayor and Corporation of Bath will never regret the outlay they have already invested. But they must not rest on their oars. It is a matter of competition, and at the present day there is no such thing as standing still. They will have to exercise a vigilant management over the hotels and lodging houses of Bath, so as to bring them to a high state of sanitation; they must provide ample attractions in the shape of music, concerts, and the rest; and they must not be above taking hints from what is done at continental spas. The increasing popularity of Bath gives promise of even a more successful future.

Annotations.

"Forsan et hæc olim meminisse juvabit."

THE PHILOSOPHER'S STONE OR WHAT!

Some of the old philosophers sought for the principle of life, for something which would keep the old from growing feeble, which would effectually arrest the ravages of time, and make the old man vigorous. This story has been worked out in many novels, but we have looked upon the alchymists as dreamers who wasted time and substance in the search after an *ignis fatuus*. The elixir of life, we now learn from our French exchanges, is within the reach of all of us.

"We have," says the *Journal de Medecine de Paris*, of June 23rd, "had many therapeutical surprises during late years: the spinal marrows of M. Pasteur, the suspension treatment of M. Charcot, the tetanus of M. Verneuil; but none of them approach the discovery by M. Brown-Séquard." We may remind our readers that Brown-Séquard is president of the Biological Society of Paris, and that he has the reputation of being one of the most illustrious physiologists of the age. His face and figure may be familiar to those who attend the meetings of the British Medical Association. Bearing these facts in mind, our readers will better appreciate the value of the following personal contribution to science made by the president, Brown-Séquard, to the Biological Society of Paris. "You have known," says the illustrious physiologist, "that for the past six months I was age-ing; a valetudinarian, I tottered, my intelligence was becoming weaker, my sphincters had lost their power—in a word I was marching gently towards second childhood. It was nothing to be wondered at, considering I was born in 1815. Look at me to-day; my eye sparkles, my speech is sure, my intelligence is re-awakened. I work in my laboratory for twelve hours a day, my sphincters perform their functions marvellously—in a word I have returned to my twentieth year." All these surprising results have been obtained in a most extraordinary way, and M. Séquard does not wish to imitate the example of the old alchymists, nor does he even imitate the example of M. Pasteur. He might have kept his secret to himself, and sold it to a company and exploited the new elixir in little glass tubes, when a fortune would have

awaited him ; because old age is creeping on everyone, and a commodity of this kind would be in universal demand, for the older people get the more foolish they get, so that clients would be ever to hand. M. Brown-Séquard is, however, above trade and making a profit out of a scientific discovery, so he tells us of the simple method he has so successfully adopted in his own person. "All the world knows," continues M. Séquard, that eunuchs are weak physiologically and morally, and we know that this weakness also exists in men who abuse the sexual power." These facts induced M. Séquard to believe that it was possible to inject, without danger, into the veins of an old man, sperm, and thus produce manifestations of rejuvenescence. This is the theory, but M. Brown-Séquard went farther and tested on himself the efficacy of the strange remedy. We give the text in French of the preparation M. Brown-Séquard used. "*Ou y broie toute la masse testiculaire, ou y agonte de 2 à 5 centim, cubes d'eau distillée, puis ou met le tout sur un filtre. Le liquide anisi obtenu est immediatement injecté.*"

We quote the text as given by the *Journal de Medecine de Paris*, lest our readers should think that this was a *canard.* M. Brown-Séquard employed twelve or fourteen injections into the lower members—one injection every day. He concluded by saying that some might assign the results to imagination ; on his part he advised all the septuagenarians to repeat his experiments, and then it would be seen whether the results were to be attributed to special idiosyncrasy or suggestion. He felt convinced that in his case the return of juvenescence was to be attributed to the nature of the injections.

Great is Diana of the Ephesians, and great is science of the present day. The lay press has taken up with *reclame* the experience and formulæ of the old physiologist, and it is not difficult to prophesy what the result will be. Young animals will be sacrified, and we shall have shortly in the market concentrated solutions of the new elixir. Professors of the art of insuring longevity will start their caravans, and with band and banner travel through the provincial towns, promising to the old a new lease of life. This is what is to be expected of the uneducated population and the unenlightened ; but we fear that, even as the suspension treatment of Charcot was taken up by the profession, we shall have a scientific discussion of the value of M. Brown-Séquard's remedy, and the septuagenarians in the profession, of whom there are a number, with incipient *ramollissement* will put to the test, purely in the interests of science, the formula of this distinguished physiologist ; and we shall have a new literature brought about by this latest discovery of science. Dr. Agerontimons, in the *Revue Génerale de Thérapeutique*, has described in rhyme the experiments of Dr. Séquard, as follows :

De merveilles sans nom ce grand siècle est témoin
Qui peut dire au progrès : Tu n'iras pas plus loin ?
Entrez au temple saint où la Biologie
S'unit à ses nombreuses sœurs en . . ologie.
Brown-Sequard y préside à soixante-douze ans,
Ecoutez sa voix ferme et ses mâles accents ;
Ils disent simplement, sa découverte immense.
" J'ai retrouvé la vraie fontaine de Jouvence ;
" Son liquide fameux coule tout près de nous,
" Comme une outre, il remplit les *Orchis* des toutous ;
" Prenez d'un chien vivant le suc testiculaire,
" Injectez sous la peau . . Serait-il séculaire,
" Le nombre de vos ans tout à coup disparaît,
" A chaque injection, la jeunesse renaît.
" La piqûre est puissante, un peu de lymphangite
" En marque les contours ; mais pour un tel succès
" De douleur cent fois pire on méprise l'accès.
" Voilà mon procédé. Quelque malin critique
" Jaloux ou pudibond le trouve-t-il cynique ?
" Du cobaye innocent il peut se contenter ;
" Le résultat est sûr, et j'en puis attester
" Le succès merveilleux de ma propre entreprise ;
" De vingt ans enlevés, j'éprouve la surprise
" Voyez le dynamo, mes muscles sont plus forts
" Et comme aux jours heureux secondent mes efforts,
" L'intestin paresseux, au dire de Voltaire
" *Inhibant* le cerveau rendrait le caractère
" Hargneux, félon, cruel ? D'après mon procédé
" Il s'exonère seul. *Citô et jucunde.*
" L'esprit en est plus leste et ma verve docile
" Ne trouve plus jamais le travail difficile.
" J'éprouve en tout mon être une nouvelle ardeur,
" Ma fibre vésicale a repris sa vigueur ;
" Cette eau qui lentement tombait, débile et molle,
" Se projette en arcade et décrit l'hyperbole.
" . . Ce premier pas est grand ! . . Vous le comprenez bien,
" Mais modeste et discret je n'ajouterai rien.—
" Pouvais-je pour moi seul garder un tel bien-être ?
" Essayez, croyez-moi. Dans un siècle peut-être ?
" Vous redirez encore à la postérité !
" Séquard est immortel et l'a bien mérité.

But M. Brown-Séquard is only at the commencement of his studies, as the following extract from *L'Union Medicale*, June 22nd, 1889, tells us :

"M. Brown-Séquard s'est., depuis la premiere communication, creuse la cervelle pour trouver comment agit le liquide testiculaire pour rajeunir anisi ceux a qui on l'injecté it a trouvé que ce liquide remplacait chez les viellards celui que leur testicules ne secrétait plus normalement. Il faut, d'après lui, pour que l'homme joeuiss de toute sa vigueur, que le testicule fonctionne, et qu'il fonctionne sans cesse. A l'appui de cette proposition, il cite le fait suivant :

Deux sujets épuisés, âgés l'un de 55 ans environ, l'autre de 63 à 65 ans, éprouvaient une faiblesse cérébrale très marquée ; afin de leur redonner de la vigueur, il leur conseilla, pour faire fonctionner leurs testicules, d'avoir recours à . . je vous le donne en mille . . à la masturbation ! oui, à la masturbation, mais incomplète et sans arriver à l'éjaculation ; il fallait bien faire fonctionner le testicule, mais il ne fallait pas priver l'organisme du produit de la sécrétion ; aussi, dès que la contraction indicatrice de l'éjaculation commençait, la manœuvre cessait. Il parait que les résultats fournis chez ces deux hommes par cette singulière méthode furent des plus favorables.

M. Brown-Séquard se propose de pousser plus loin ses expériences et de prendre la femme comme champ d'action. Entendons-nous.

On sait que les femmes auxquelles on enlève les ovaires de deviennent comparables, au point de vue de la vitalité générale, aux hommes auxquels on a enlevé les testicules ; se sont de véritables eunuques. Par conséquent, les ovaires exerceraient sur la vitalité organique la même influence que les testicules ; partant de cette donnée, M. Brown-Séquard, s'est demandé s'il ne serait pas possible d'obtenir chez la femme des résultats comparables à ceux qu'il a constatés sur lui-même, en employant chez elle du liquide obtenu par la trituration des ovaires. Il va commencer prochainment ces expériences, mais il serait heureux qu'elles fussent faites aussi par d'autres que par lui, par exemple, par des femmes-médecins sur leur propre personne ou sur d'autres femmes.

ESSENCE OF THE PROCEEDINGS OF THE MEDICAL COUNCIL.

It is a matter of very great interest to the profession as to whether the president of the Medical Council should walk behind the president of Royal College of Surgeons, or whether the Royal College of Surgeons' president should walk behind the president of the Medical Council, so the matter in dispute has been submitted to the most eminent authorities, and we may expect, within a few years, to have the due order of precedence set down in the official book of etiquette. This occupied part of the time of the Council. It does not represent a fair sample of the business done during the session, which was a short one. The want of funds is oppressing the Council, and for this reason they have suspended the visitation of examinations. They may make money out of the Pharmacopœia, which they certainly would not do if they allowed open competition, as in the work, a prospectus of which has been issued, and of course the Council have the power of applying for an injunction. The address of the president was short, thereby saving many pounds a day; the judicial functions of the Council had been exercised with fairness, and we believe that, in consequence of the determination shown by the Council, a number of sinners have repented, and tried to walk within professional lines. Penal discipline is unfortunately necessary, but justice to the accused requires that thorough investigation should take place, and this is costly, as we believe the whole Council have to sit and determine whether erasure from the Register should follow on professional delinquency. The proposal in favour of students learning shorthand is negatived. The suggestion that we should have hospitals for the treatment of insanity, is one that must commend itself. At present we have asylums, and this term explains itself. A medical superintendent who has the charge of 1,400 patients, and the management, even with excellent assistance, cannot treat insanity. He is weighed down by his multifarious duties. The examinations, conducted as they have been, piecemeal, admit of reform, and the Council very properly took into consideration the extreme subdivision of the examinations, so that we may expect some change to be made in this respect. Again the subjects on which the students are examined are not wisely selected, too little attention being paid to what we might call the practical class of diseases, with which the student, in after life, will be occupied. Lectures have been the usual means of instruction, and clinical lectures are simply invaluable. There are, of course, lecturers *and* lecturers; unfortunately a good lecturer is a rarity.

Of course, it is easy to find fault with the lecture system, but it is much more difficult to suggest a remedy. We should certainly say that greater development should be given to the clinical lecture, the patient being shown not necessarily at the bed-side, but in the theatre. A lecturer should not read a long paper, he should be able to speak extemporaneously, of course, from a few notes. At the clinical lecture interest is always maintained when the lecturer is able to speak in a conversational way. There are a few other subjects of minor importance, which came before the Council. The minutes are now published, and may be obtained from the Registrar, Medical Council Office, Oxford-street, London.

RECENT RESULTS OF THE PASTEUR TREATMENT.

The period of incubation in hydrophobia averages, as a rule, from forty to sixty days. The following case is taken from the *Journal de Medicine de Paris*, May 26th. O. S——, decorator, was bitten in 1886 by a dog suspected to be rabid, and immediately killed by its owner. O. S—— immediately went to Paris, and was treated *secundum artem*, and discharged "cured." We regret to state that O. S—— died last month of hydrophobia, three years after the bite. The owner of the dog was bitten at the same time on the finger. He did not go to Paris, contenting himself with immediate cauterization. The remarkable period of incubation, three years, in this reported case throws into strong relief the singular nature of the poison we have to deal with in hydrophobia.

On the 27th October, 1887, *un garcon* named Dupont, living at 114, Boulevard de Belle Ville, was bitten by a dog supposed to be mad. He was taken to a pharmacien, who in place of cauterizing the wound applied an alkali, Dupont then went to the Pasteur Institute, and was discharged after some days of treatment cured. We learn from the *Journal de Medicine de Paris*, June 16th, that Dupont was sent to the Hotel Dieu suffering from hydrophobia, some time in June.

THE PARIS EXHIBITION.

Those who visit Paris, and we presume that a number of medical men will take their holidays there, should be particular about drinking the ordinary table water unless they like liquid sewage. The great concourse of visitors to Paris has necessarily involved the use of a large quantity of the water, and the Seine has been, and will no doubt be, utilized. The best plan is to drink Apollinaris or some other mineral water, Maçon or other sound French wine.

BLACK-MAIL, OR GRASP YOUR NETTLE.

One of the latest instances of black-mail is that made upon Malcolm Morris. He is to be congratulated upon his courage in turning the tables upon his persecutors, and we are pleased to see that a number of his professional brethren have joined in an expression of their regard for him, and of condolence at the annoyance to which he has been exposed. It is an old saying, "Grasp your nettle," and in dealing with black-mailers this is the plan. We fear that too many are inclined to hush up matters of this kind, through dread of publicity. Innocent men have consented to pay black-mailers, thereby encouraging the system. The black-mailer who has once tasted money will try his hand at another victim. Mr. Morris by his action has deserved well of the profession.

THE PENNY A WEEK COLLECTION.

The penny a week collections asked for from the working men as their contribution to the London Hospital is not as fully appreciated as its promoters expected. The *Philanthropist* summarises some of the objections:

1. The working classes already contribute more than their share to the hospitals.

2. The people who derive the greatest benefit from these institutions are the students and the wealthy classes, for whose benefit the poor are subjected to all sorts of experiments.

3. Working men, if they contribute, ought to exercise control.

4. The penny a week would in practice become compulsory.

The Lord Mayor has replied that a half-penny would be acceptable, but there is no compulsion. "If a man feels that 4*s.* 4*d.* or 2*s.* 2*d.* (?) a year for medical and surgical advice of the highest order, (?) and as much medicine as may be required, is an exorbitant contribution—if he prefers to rely upon charity, there is nothing in the Lord Mayor's project to prevent him."

CREDULOUS PEOPLE.

It would be hardly fair to brand the clergy of all denominations with being supporters of quackery, but there is sufficient justification for complaints made by the press of America, France, and England, that clergymen are to be found in large numbers who endorse and support quackery. We have under our eyes a full page of advertisements in a weekly paper, setting forth the virtues of the medicines sold by Sequah, Sequah being a shrewd American who is now exploiting Yorkshire. Sequar speaks to the halt and the lame, and to the incurable; and in this advertisement there is one column headed "The Churches speak." In this column are given the letters of a number of clergymen, amongst whom we find the following:—W. Wilson, minister, North Parish, Aberdeen; James Burton, St. Andrew's, Aberdeen; Dr. Jamieson, Old Machar Cathedral, Aberdeen; Andrew Inglis, Lochee, Dundee; J. B. St. Clair, minister, Aberdeen; James Dewar, minister, Aberdeen; Parker Noble, Jerry-road, Dundee; S. Smith, assistant priest, St. Margaret's, Dundee; Father Macdonald, Lochee, Dundee; A. Alexander, Dundee; James A. Russell, Aberdeen; Father Forder, St. Patrick's, Sunderland; C. V. Gee, St. Columba, Sunderland; J. W. Willink, St. John's Vicarage, Sunderland; Father Callanan, St. Joseph's, Sunderland; W. Berbery, C.C., St. Mary's, Sunderland; T. Jones, The Vicarage, Newport, Mon. These are a few of the names, and we really are astonished to find men, presumably educated, giving testimonials to a peripatetic charlatan, whose band and carriage gives proof in itself of his trade. We may fairly include these clergymen under the head of the credulous, and when we find pastors of this kind, we cannot expect much better things of their flocks. The working classes who make up the crowds which surround the caravan can afford four shillings for two small bottles, though they cannot afford to pay four shillings a year for the medical and surgical aid they receive at the local infirmaries. It is a very sad state of things, and affords ample food for moralizing.

THE LABORATORY FOR WORK.

Where is the best laboratory for the study of disease? Does England want more laboratories? Or,——but we must not ask too many conundrums. The best laboratory for the study of disease is in the hospital ward, or in the sick chamber, and we hope that shortly we shall have some words on this subject from some teacher of eminence. The ward or bed-side is the place for study; all else is simply supplementary—just as the test-tube, microscope, etc., are. Experimental pharmacology outside the sick room has not given us much; bacteriology or the laboratory have not given us much. When we compare the work of the clinicians with the work of the present day, we can only say: "These old clinicians were men; when shall we see their like again?"

SHORTHAND FOR MEDICAL STUDENTS.

Medical students have to attend a large number of lectures, something like a thousand in number; they have to take notes of these lectures, and presumedly it would be an advantage if shorthand could be used in the process. Considering that a large number of these lectures are not even worth the trouble of taking notes, it is a matter of question whether it would be worth the student's while to learn shorthand simply for this purpose. But shorthand might be applied to other purposes than simply taking notes of lectures; and we believe that it would be of great use in after life, not only for purposes of medicine, but for making entries of all kinds.

MEDICAL SICK AND BENEFIT SOCIETY.

The Society continues to flourish, and the balance sheet and tables should be read by all members of the profession. It is a very extraordinary thing, that the *Lancet* has almost completely ignored the Society. Lately the *Lancet* has offered the sum of £300 a year for distribution amongst poor members of the profession. It would be much better if the *Lancet* gave encouragement to thrift and providence by setting forth the advantages of this Society before its readers. We look upon the donation of the *Lancet* as simply a journalistic effort to increase its circulation, and we are astonished that the President of the Royal College of Surgeons should have accepted the position of almoner to a fund of this nature. There is no reason why such a thing should have been established, seeing that we have a medical benevolent fund. The *Lancet* could have, of course, given £300 a year to that, but it would not have obtained such kudos or publicity. Members of the profession who desire to provide for sickness and accident, should write for prospectus to Mr. C. J. Radley, 26, Wynn-road, Brixton, London.

M. PEYRAUD'S EXPERIMENTS.

ABOUT a year ago Dr. Peyraud, of Libourne, presented to the Academy of Medicine, Paris, a very important *memoire* on tanacetic rabies. In this paper were formulated for the first time the good effects of injections of essence of tansy for the cure of rabies. Essence of tansy produces simili-rabies, and a vaccine equal to that of Pasteur was said to be made from the tansy-rabies. Dr. Peyraud termed this chemical vaccine. "What progress would be realized," says the editor of the *Gazette Hebdomadaire des Sciences Medicales de Bordeaux*, "if we could suppress all the strange and difficult processes of the Pasteur Institute. With a simple flagon of essence of tansy, which could be procured in every part of the globe, rabies could be controlled without exposing the patient to inoculation." M. Trasbot was charged by the Academy with the duty of controlling Dr. Peyraud's experiments. He has reported to the Academy as follows: (1) Essence of tansy injected into the veins, in certain doses, produces in the rabbit a form of poisoning, symptoms of which resemble those of rabies. (2) Solution of chloral, 10 per cent., mixed before inoculation with the rabic virus, appears to diminish and even to destroy its virulent properties. (3) Essence of tansy injected at the point where rabic inoculation has been practised appears to prevent the development of rabies in a certain number of animals—four out of six—whilst in the test animals inoculated under the same conditions only one out of six survived. These figures appear favourable, in a certain measure, to the opinions sustained by Dr. Peyraud. The commission concluded by thanking Dr. Peyraud for his interesting researches, and to continue them so as to bring about greater accuracy.

PROVINCIAL DINNER OF THE IRISH MEDICAL SCHOOLS AND GRADUATES' ASSOCIATION.

A MOST successful meeting of the above Association was held at Queen's Hotel, Manchester, on June 19th. Drs. Macnaughton Jones, Gilbart-Smith, Abrahams, Fegan (London), represented the London contingent; whilst the provinces were represented by Drs. Leslie-Jones, Stewart, Daly, Dolan, Owen, etc. The general meeting was held at five p.m., under the presidency of Dr. Fegan. Owing to the sudden and lamented death of Dr. Robert Macdonald, there was a vacancy, and Dr. Kidd was appointed president elect. The dinner took place at the Queen's Hotel, and was well attended. Amongst those present were the leading practitioners of Manchester, and the neighbourhood. The usual toasts were proposed, and in response to that of the visitors, the Mayor of Salford responded. The Manchester meeting has been the means of bringing the Association prominently before the Irish practitioners of Lancashire and Yorkshire, and will, in time, result in a large accession from the northern district to the strength of the Association. An admirable selection of music was contributed by some friends of Dr. Daly during the dinner.

THE ELECTION AT THE ROYAL COLLEGE OF SURGEONS.

THE present election of the Council of Royal College Surgeons is a most important one, and we trust that the provincial Fellows will do their duty and elect provincial Fellows. We direct attention to the letter of Mr. Steele. It is now too late to enter into an explanation of the reasons why provincial Fellows should be elected, as we presume that, by this time, most of the voting papers have been sent in. The party in favour of the reform would be much strengthened by the return of Mr. Lawson Tait.

LEPROSY.

WE trust that there will not be a scare about the leprosy, as there has been about cancer and rabies. Undoubtedly something must be done in India, not only in the interest of the lepers themselves, but of the communities which have international relations with India. The testimonial to Father Damien, promoted by all sections and classes in England, will no doubt result in greater benefit to this unfortunate class of sufferers, and we may expect that, in India, Lazarettos will be established where they will have proper medical care and supervision.

THE BRITISH GYNÆCOLOGICAL SOCIETY.

THIS Society has exceeded the expectations of its founders, and at the present time, in point of numbers and financial results, leaves nothing to be desired. It may be regarded as an overflow from the Obstetrical Society; it is not by any means related to the Obstetrical, and we fear that the older Society does not look very approvingly upon the British Gynæcological. This is very much to be regretted, for there is ample room for both Societies. Obstetrics cover a very wide field, and it is impossible for an obstetrical society to adequately do justice to gynæcology. The Obstetrical Society has done excellent service in its time, and may still continue to advance the interests of the diseases of women, so far as they are confined to the puerperal state, but the British Gynæcological Society stands in a very different relation to the advancement of the study of diseases of women. It leaves the obstetric field to its rival, and deals with surgical diseases, and what is included under the proper heading of gynæcology. An obstetrician is not necessary a gynæcologist. We know that gynæcologists such as Tait, Bantock, etc., decline to have anything to do with obstetrics. This division of labour does not suit a few obstetricians, and it is thought that the Obstetrical Society afforded ample field for both obstetrics and gynæcology. It is very remarkable that there should be any difference of opinion on a matter of this kind after the experience we have from America. We write with regret, that the Americans are ahead of us in dentistry, and in gynæcology. Though we have individuals, who are ahead of them in all that relates to operative skill, but generally our statement is correct. The reason is that gynæcology was separated from

obstetrics, and its study put on a proper basis. Excellent handbooks as those of Thomas, Mundè, Goodall, have been published, and are to be found in every practitioner's library in the States. The Americans took up this study with all the energy of a young people, and we are simply following in their wake, and attempting to interest general practitioners in a branch of practice which is the most important one to them. There is always a little difficulty in launching out a new society. Even in the practice of medicine there are jealousies, but the British Gynæcological Society had even less difficulty than was anticipated. It evidently met a want; hence its hundreds of members; hence the success of its meetings and its transactions. Opposition and competition are excellent things; they stimulate to action; and the best thing for the British Gynæcological Society would be personal antagonism, as we feel sure it would stir up those who are interested in it to make it a still greater success.

New Remedies.

A method of obviating the inconvenience arising from the acidity of alkaloidal salts, when used in ophthalmic practice, has been suggested by M. Petit. When combined with boric acid the salts are distinctly basic, and the small quantity of boric acid set free in consequence of decomposition, as is the case with atropine and its isomers, as well as cocaine, would always be more than saturated by this excess of alkalinity. The borates are prepared by dissolving one part by weight of the alkaloid—*e.g.*, eserine, pilocarpine, atropine, hyoscyamine, or cocaine—in a little alcohol, and then adding two parts by weight of alkaloid separately dissolved in alcohol, mixing the two solutions and evaporating to dryness.

Under the name of *papier iodogène* a preparation has been introduced by M. Eymonnet as a substitute for iodized cotton in applications of the tincture of iodine. This preparation has the advantage of gradually giving off iodine when moistened with water. It consists of one sheet of paper impregnated with a mixture of potassium iodate and tartaric acid and dried, and another steeped in a solution of potassium iodide and dried. Between these two a thin sheet of paper is placed, and the three are stuck together. When required for use the *papier* is moistened and applied with a covering of sheet gutta percha. The tartaric acid attacks the potassium iodide, liberating hydriodic acid, and this reacts with the iodic acid from the iodate, setting free the iodine. A sensation of warmth is experienced, due to the revulsion set up by the nascent iodine. This sensation gradually becomes stronger, but is tolerable for the forty-five minutes during which the reaction lasts. When the reaction is over the paper becomes of a straw-yellow tint.

Pyciranthemum linifolium, popularly known in the United States as Virginia thyme, has lately been recommended by H. T. Painter as a remedy in dyspepsia, dysentery, and other intestinal affections, and as a useful diaphoretic. The fluid extract is prepared with a mixture of one part of alcohol and three parts of water. This preparation is, however, liable to deposit after some weeks, and a syrup is therefore preferred.

Antipyrin seems to be found more useful day by day. One of the most recent discoveries in connection with it is its favourable action on diabetes, which has lately been discussed in the Academy of Medicine at Paris. M. Panas found that daily doses of forty-five grains completely stopped the secretion of sugar, but that when the dose of antipyrin was decreased the sugar again appeared in proportion as the amount of antipyrin was diminished. In eighteen cases M. Germain Sée had found it to act favourably, the thirst and the symptoms in skin and nerve being lessened at the same time. M. A. Robin found that some starchy food might even be given with antipyrin, and that the administration of the drug was especially useful in cases which were of long standing, and in which the strict dietary was found very irksome. It appeared, however, to do more harm than good in cases where there was swelling of the eyelids and much emaciation and pallor. Antipyrin has also been found useful as an application to hæmorrhoidal ulcers.

A new reagent for detecting sugar in urine has been found in safranine, which is said to possess the advantage of not being decolorised by uric acid, creatinine, chloral, chloroform, peroxide of hydrogen, or the salts of hydroxylamine, all of which reduce Fehling's solution. Albumen, however, does decolorise it. The process recommended is to boil 1 cc. of the urine with 5 cc. of a solution of safranine of the strength of 1 in 1000, and 2 cc. of a solution of caustic potash. If decolorisation is effected the urine is diabetic, normal urine containing too little sugar to decolorise completely so much of the reagent. Chloral and chloroform do attenuate the red colour of the safranine, but never completely destroy it. Chloride of barium has been found by Dr. A. N. Hare to act as rapidly as digitalis in slowing the heart, contracting the blood-vessels, and increasing the blood-pressure. He states that it does not act as an irritant poison unless the dose be many times larger than the medicinal one. In five cases of vulvular affection of the heart, and two of functional disturbance of that organ, it was found to act beneficially by Dr. Hare.

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. Kesteven, M.D.

A Case of Leontiasis ossium (Elephantiasis leonina). By B. Frankel (*Centralblatt für Chirurgie*, May 11th).—A girl, twelve years of age, had, until within the last four years, been in good health, save that in infancy she was ricketty. Her parents were both dead. Four years ago a tumour appeared on her forehead, hard and painful, in which state it remained two and a half years. At the date of the present observation two large hard lumps are visible on the forehead. The nasal processes of the superior maxillæ are on both sides so much enlarged that the ridge of the nose is not apparent. The zygomata processes are notably thickened and enlarged; the inferior maxilla is changed into a thick hard mass. The nose is entirely displaced by the thickening of the nasal processes of the superior maxilla, the septum, and muscles of the nostrils. The possibility of hereditary syphilis being suspected, iodide was given in full doses without any result.

On Drilling Capillary Holes through the Skull for the purpose of Exploring with the Hypodermic Needle. By Edmond Souchon, M.D., Louisiana (*New Orleans Medical and Surgical Journal*, May, 1889).—Possibly our readers may feel some surprise at the following statement by Dr. Souchon: "It is a recognised and accepted surgical practice to explore the brain in doubtful cases, just as the abdomen is explored by exploratory laparotomies in all cases of doubt when the doubtful points involve extensive and dangerous surgical procedures."

The object of the paper under consideration is the penetration of the skull to reach the brain and its interior. Heretofore the operation has consisted in trephining the suspected spot and exploring the subdural spaces and the brain, a proceeding very often used when too late.

"Fully impressed with the importance of early diagnoses in these cases of brain trouble particularly, it occurred to me that it would be possible to substitute for the apparently formidable application of the trepan the simpler, readier, less formidable, and less dangerous procedure of drilling through the skull a small hole, only large enough to introduce a hypodermic needle.

"With this idea in view I proceeded to test the idea practically on dogs. All the rules of strict antisepsis and of location of the spots for operation which have to be observed for trephining were followed here and strictly adhered to. The animals were placed under chloroform specially with the view of controlling them and keeping them perfectly quiet. The spot to be explored was shaved of its hair by a clip of the point of the scissors, and the place well washed and rendered aseptic. Then with a sharp-pointed aseptic bistoury a hole was made through the soft parts of the scalp. Through this the bit of a watchmaker's drill

was introduced, and as soon as it had reached the bone the instrument was held firmly pressed against the bone, and the sliding knot of the instrument worked, at first slowly, then swiftly, and again slowly as the bit penetrated the bone and came near the brain substance. As soon as the skull has been penetrated the drill is withdrawn, and a hypodermic needle with syringe introduced. The needle should be *twice as large* as the ordinary needle of our cases, so that if it should strike the thick pus of an abscess, or the thick fluid of a cyst, the calibre will be large enough to suck it, which it will surely not do if the needle is as fine as the one ordinarily used for a hypodermic injection.

"This procedure was performed twice on each side of the middle line of the skull on two dogs. Each time the needle was driven to the hilt within the tissues, the distance from the point to the hilt being about an inch and a half. The dogs were afterwards left to themselves. Both recovered rapidly from the effects of the chloroform, and behaved as naturally afterwards as if their skull and brain had not been perforated four times at different places.

"After a rest of two weeks the animals were again put under chloroform, and again the skull and brain were drilled and explored in four places. The result was exactly the same as at the first sitting. They recovered rapidly. The dogs were kept about the yard for several weeks to see if any remote effects would develop, but none were noticed."

The Pathology of Diabetes (*L'Union Médicale*, June 1st, 1889).—The two opposing theories of the pathogenesis of diabetes, the hypersecretion of sugar and its deficient consumption in the system, have formed the subject of a discussion at the Academy of Medicine, Paris. M. Albert Robin (after Germain Seé) supported the theory of hypersecretion, or exaggeration of the amount of sugar eliminated with the urine. M. Robin supported his opinion by an appeal to chemical biology, as advanced by himself and other experimentalists—MM. Lépine, Henoeque, Quinquam, Charcot, and Brouardel—and showed that diabetes coincides with certain organic activities, especially of the liver and nervous system. This view M. Robin holds to be confirmed by the effects of remedies. Antipyrine, quinine, arsenic, opium, etc., which control the organic changes in diabetics, diminish glycosuria, whilst those remedies which accelerate nutrition augment glycosuria. The former, therefore, should be prescribed, and the latter proscribed, in the treatment of diabetes. M. Bouchard adduces conclusions, from his own researches, entirely opposed to those of M. Robin.

Manual Evacuation of the Bladder. By Heddans (*Centralblatt für Chirurgie*, April 27th, 1889).—In cases of paralysis of the *detrusor vesicæ* the urine may be expelled by the following manipulation. The patient lying on the back, and both lower limbs bent upon the abdomen, pressure may be made by two hands over the region of the bladder, very gradually increased, the practitioner standing behind the patient. Under this method it often occurs that the urine will flow in a full stream. The operation can be practised in almost every case where catheterism is admissible. It is contra-indicated in inflammatory conditions of the abdominal organs and pregnancy; in such cases catheterism should be practised. Caution must be observed that the distended bladder be not ruptured.

The Importance of Manure Heaps and Poultry in the Etiology of Diphtheria (*New Orleans Medical and Surgical Journal*, May, 1889).—It has been recognised that diphtheria is *par excellence* the infectious disease of rural districts, and has given rise to suspicion that domestic animals, perhaps, suffer from an analogous disease, with which the human species can be infected. Poultry are subject to a disease, characterised by false membranes on the mucous surface and by visceral lesions, which present the greatest analogy to diphtheria.

Ferrand (*Thèse de doctorat. Lion, 1885*) has collected the statistics of this disease, and finds that in Scotland, 21.6 cases occur in urban, and twenty-seven in rural districts amongst every 100,000 inhabitants. The same holds for Prussia and Russia. Whilst about Lyons it is noticed that the country districts suffer most, the suburbs less so, and the urban districts least of all. This distribution is explained by the accumulation at the entrances of large towns of scavengers' refuse, manure, etc.; and that at the doors of the country houses there are manure heaps, where poultry affected with "pip" (pépie) spread the disease. Klebs noticed in 1883 that diphtheria breaks out, as a rule, the day after sweeping the streets of a town, and principally on the routes followed by the carts removing the refuse.

Hydrate of Chloral in Chapped Nipple (*St. Louis Medical and Surgical Journal*, May, 1889).—In the *Jürnal Aküsherstva i Jenskikh Bolenzèi*, December, 1888, p. 892, Dr. Ivan A. Mitropolsky, of Moscow, highly recommends chloral as an excellent local means for fissured and excoriated nipples. The latter soaked in a solution of half a drachm of chloral in three ounces of water. The compresses should be changed every two and a half or three hours. When a prolonged application is necessary, it is advisable to use a weaker lotion (half drachm to six ounces). The solution leaves a thin, whitish, firmly adherent film over the diseased surface, which does not disappear by suckling. Pain and tenderness are said to be strikingly relieved almost immediately; the lesions rapidly healing. The chloral compresses do not produce any bad effects of nurslings. [It surely does involve some risk to infants should chloral remain on the nipple?]

Spontaneous Cure of an Aortic Aneurism. Vagel, Freiburg-on-the-Elbe (*Centralblatt für Chirurgie*, May 25th, 1889).—The patient, a young man, in the spring of 1881, presented all the signs of an aortic aneurism. The size could not be precisely determined, but was apparently that of a large apple. The patient was confined to his bed through pain. All the means he had recourse to proving useless, he was admitted into the hospital, where it remained unaltered two months. Six months afterwards, under the "hunger-cure," improvement commenced; the pulsation subsided; the tumour gradually disappeared. Six years afterwards the patient is still in good health, and capable of work. [*Query*—Was the diagnosis correct?]

On Iodoform-ether Treatment for Tubercular Inflammation of Bone. By Dr. Dallinger, Bucharest (*Centralblatt für Chirurgie*) May 18th, 1889).—Dr. Dallinger finds results so different given that he has thought it desirable to collect some experimental observations with reference to the effects of injection of iodoform-ether in inflammation of the bones. Verneuil, he observes, states that the great advantage of this treatment is that it is free from danger. This statement has, however, been more lately controverted. In one instance the injection was followed by prolonged sickness and narcosis of several hours' duration. In another case the injection was followed by unconsciousness, cyanosis, and dyspnœa. The patient remained stupified for two days. The injection used in a case of lumbar abscess was followed by retention of urine thirty hours, and vesical catarrh for upwards of ten days. In a case of psoas abscess the injection was followed by a burning sensation which continued for one or two minutes, and was followed by a state of mental oppresion lasting four hours, when the pain in the lumbar abscess extended to the knee, continuing from eighteen to twenty hours, and the subsequent occurrence of headache and inclination to vomit. Dr. Dallinger holds, therefore, that the injection of iodoform-ether is free from danger.

Right-sided Aphasia in a Left-handed Person (*The Times and Register*, New York, May, 1889).—H. C. Wood, M.D. (*Medical News*), says this case has seemed to him worthy of being recorded on account of the curious relations between the habitual use of the hands and the speech function. The aphasia was the result of a lesion in the left side of the brain. Although the person was for the ordinary purposes of life left-handed, he had always written with the right hand; the centres connected with writing, in locating themselves, so to speak, had followed not the centres of habitual physical action, but the centres of speech function. In other words, this man possessed a brain in which the speech centres were highly developed in the left hemisphere, although the motor centres for the hand and leg, and probably for the face, were more highly developed in the right than the left hemisphere, and in which, when the art of writing was learned, the motor centres of the left hemisphere underwent special development, apparently on account of their close relations with the centres of speech.

Treatment of Rabies by Essence of Tansy (*Journal de Médicine de Paris*, June 9th, 1889).—M. Trasbot submits the following conclusions to the Academy of Medicine:—1. The essence of tansy injected into the veins of rabbits produces symptoms of rabies. 2. Ten per cent. of chloral destroys the poisonous properties. 3. The essence of tansy, injected around the point of injection, of virus of rabies, hinders the development of that disease in a certain proportion of cases (four out of six). It would seem, therefore, that this method is more efficacious than M. Pasteur's injections; at the same time they are confirmatory of the conclusions of M. Peyrand, that the artificial production of rabies prevents the evolution of the disorder.

Accidents due to Mussels, attributed to Microbes (*L'Union Médicale*, June 1st, 1889).—M. Lustig has found in the larvæ of mussels, that had been collected from stagnant waters, and which had caused death in from twelve to twenty-four hours after they had been taken, two different micro-organisms, the one harmless, the other pathogenic. These last produced no ill effect when injected into the veins, but caused death in from twelve to forty-eight hours when introduced into the stomachs of rabbits or guinea-pigs. M. Lustig finds that poisonous mussels have afforded homes to a dangerous microbe, but that the disturbances caused by these are owing to ptomaines of microbic origin rather than to any infectious malady.

On General and Cutaneous Poisoning by Petroleum (*Centralblatt für Chirurgie*, May 11th, 1889).—L. Levin gathers from literature, and from his own experimental researches, that petroleum can only, in a limited sense, be regarded as a poison, and that only when adulterated with other oils. The prolonged action of petroleum upon the skin of persons engaged in petroleum and oil-springs, induces an eruption of acne, distributed in all parts of the face, hands, arms, and legs, On the scalp the disease may be seen in various stages of inflammation and suppuration, intermixed with numerous black comedones, scurf, and sebaceous crusts. In America the author had seen this disease of the skin only among the workers in the refuse petroleum after the separation of illuminating oils.

A Peculiar Wart near the Ear (*Centralblatt für Chirurgie*, May 11th, 1889).—Hr. Barth relates the cases of a girl, twenty years of age, who presented on the edge of the lobe of her right ear a warty growth of the size and appearance of a nipple. On the bosom of the corresponding side a deeply-pigmented areola was to be seen. The tumour was erectile and wont to swell at the menstrual periods. A similar erectile state of the integuments of the glabella, but not to the same extent, also existed. The author is inclined to regard this growth as a supernumerary nipple. Notices of such growths on the anterior aspect of the chest, on the acromion, and on the upper thigh, have been given in the works of Leichtenstern and Neugebauer.

Trichorrhexis Nodosa (*St. Loais Medical and Surgical Journal*, May, 1889).—This disease, also known as Beigel's disease, is one which is rarely seen. Dr. Richard Cole Newtown describes a case in the New York *Medical Record*, and suggests as a more proper name, the term nodositas crinium. As is well known, the appearance presented in this disease is one in which the hairs appear to have nits upon them.

Trichorrhexis Nodosa, or Nodositas Crinium.

There is a broom-like fissuring of the shaft of the hair, which is well shown in the fig. The condition was first noticed in 1878, the affected hair being chiefly at the corners of the chin, and over the rami of the jaw, in a medical. The patient was neurotic, and he, as well as the reporter of the case, is inclined to regard the condition as of nervous origin, in this case at least.

[We have met with an instance of this disease of the hair closely analagous to the preceding, and in which the microscopical character was identical.—*Rep.*]

II.—SELECTIONS FROM CONTINENTAL MEDICAL JOURNALS.

By G. F. Cadogan-Masterman, M.D.

The Treatment of Disease by Bacteriotherapy. By Dr. Luis Manfredi (*Giornale Internazionale delle Sciencie Mediche*)—Continued from page 369, June, 1889.—In our last number a summary of part of Dr. Manfredi's paper was given, as far as the abortive experiments of Cavagni's in the treatment of tuberculosis by modified cultivations of its special bacillus. This idea has been carried a step farther by Professor Cantani, of Naples, and in the direction of a true bacteriotherapy—that is, the destruction of the disease germs by the introduction of others which indirectly attack them by contaminating the tissues they feed upon, and yet in such a way as to be harmless to the patient. The form selected was the *Bacterium termo*, which, from numerous experiments upon animals, had been found free from injurious action, either within their organism or that of man. And it is, moreover, easily obtained and cultivated in peptonised broth at the temperature of 37°C. The bacterium was isolated, cultivated for twenty-four, or, occasionally, for forty-eight hours, and then injected into the lungs of the patient by means of a hand sprayer.

The first case was that of a woman in an advanced stage of consumption, with a large cavity in the superior lobe of the left lung, a moderate temperature, severe cough, and copious expectoration, containing broken-down elastic tissue and abundance of the bacillus of Koch, and with progressive emaciation. All other treatment being suspended, inhalation of the atomized broth containing the *B. termo* was practised three or four times a day. The remedy, far from being disagreeable, was gladly welcomed by the patient, and did not occasion the slightest disgust nor inconvenience during the lengthened period of its employment. In a few days its advantages were evident, the expectoration lessened and finally ceased. At first the *Bacillus tuberculosis* was found in quantity in the sputum, then it was mixed with the *B. termo*, and at length the latter had entirely replaced it; the fever diminished *pari passi*, and the patient gained more than two kilogrammes in weight.

In succeeding cases Dr. Cantani obtained results equally brilliant—not, however, without some failures. A gentleman of Catania, after treatment in the city for only four weeks, returned home apparently cured; without feverishness, cough, or a trace of the bacillus; and he had gained in that time three kilogrammes in weight. Another patient, who was so ill that he had been obliged to give up all business engagements, was enabled, after nine weeks of the cure, to resume them, feeling perfectly well and as robust as before his illness. In his case, seven kilogrammes was the weight gain. Then there was the case of a poor woman, who had the disadvantage of being treated as an out-patient, with a large cavity in the left apex. The cough was relieved, the primary bacillus disappeared from the sputum, and the cavity, although it did not seem to lessen, became dry.

The announcement of these results was received in the scientific world with the deepest interest, and a number of experimenters sought, on the one hand to confirm, and on the other to discredit them by adverse criticism. Dr. Salama, of Paris, tested the treatment in a case of advanced phthisis in a woman who had suffered from broncho-pneumonia, followed by caseous deposits, extensive infiltration, and a small cavity in the left lung. The sputum contained abundance of *B. tuberculosis*, there was high fever with morning and evening exacerbations, extreme debility, colliquative diarrhœa, and great emaciation. All the more usual modes of treatment had failed, and bacillated spray was tried as a last resource. After five days it was found that the fever was high only once daily, and that the temperature was less; that the cough was diminished, and that the *B. termo* was replacing the *B. tuberculosis*. By the fifteenth day the latter had entirely disappeared from the sputa, the general condition of the patient had improved, the cavernous bruit was less marked, and the vesicular murmur could be heard in areas in which it had been previously absent. The patient was beyond cure, but the treatment had converted a distressingly acute case into one of a gentle progress to the inevitable end.

On the other side we have the experience of Sormani. He tried the system in three cases; in neither did it seem to do any good, and in one was distinctly injurious. He considers that the inhalation of the broth itself only acts palliatively in relieving the cough, dyspnœa, and difficulty in expectorating.

But it should be remarked that all the patients of Sormani, and, indeed, of all who have not obtained the same results as those of Cantani, developed a phenomenon entirely absent from the *clinique* of the latter—*the great repugnance they displayed to the treatment itself.*

For instance, amongst eight whom Dr. Ballagi so treated, not one was the better for it; the cough, the fever, and so on, were unaffected; and one was attacked by diarrhœa, which only ceased with the cessation of the inhalations; and the other lost appetite and complained so much of the nauseous taste and odour of the broth that it was obliged to be abandoned.

Stacklevicz and Iilipovitch report results more serious still. The former treated three patients by two daily inhalations of a pure cultivation of *B. termo*, diluted with warm water, and lasting six minutes. One of these died on the sixth day with symptoms of severe gastric disturbance; the two others endured the treatment for twenty-two and thirty-three days respectively, with no improvement whatever in the symptoms, but with loss of appetite, nausea, actual vomiting, and other stomach troubles. Iilipovitch treated six cases, using 5 c.c. of broth containing a pure cultivation of the bacillus, diluted with 10 c.c. of tepid water aromatized with essence of peppermint to cover the offensive odour, twice daily. Of these one become so much worse by the eighth day that the treatment had to be abandoned, and three others died between the fifteenth and twenty-fifth day. The remaining two fled from the hospital, after enduring the treatment for seventeen and forty-two days, preferring to die by natural means.

In complete contrast to this we have a paper published by Dr. Primrose Wells (of New York?), with the history of five cases with excellent results; he found in each considerable improvement, and that the treatment *relieved the diarrhœa and improved the appetite*, and that it is of great value in all but the most advanced cases.

There can be but one conclusion: *That they did not employ the same agent.* The bacillus used by Cantani in Naples, and Salama in Paris, was not the same as that cultivated by Stacklevicz and Iillipsvitch in Odessa; or, if the same, then it must have undergone some profound change in its characteristics. The identification of these minute organisms is difficult at all times, and made the more so by the fact that the form and even reaction is not permanent. *Bacillus termo* itself, for instance, may be colourless when cultivated in gelatine, and have its usual rose tint when grown on slices of potato. It is the bacillus *in excelsis* of putrifaction in one form, it is said, and has nothing whatever to do with it in another.

And it is hard to believe that under these latter conditions we are really dealing with the same body if reactions are to be relied upon for differentiation. And it is harder still not to believe or, at least, to avoid the suspicion that in these absolutely contradictory cases two bacilli were dealt with, and that the true *B. termo* was really only used in those in which the broth had become putrid and horribly offensive, because it is essentially the rôle of this very organism to set up putrifactive changes in liquids or bodies which can undergo that offensive form of metamorphosis. We are assured in each case that *pure* cultivations alone were used, but when dealing with bodies so extremely minute, and having such strong general resemblances, the possibility of mistake is very great, without resorting to the rather lame explanation that the action of the bacillus is made variable by environment.

Maffuci and Flora tried the experiment of injecting the *B. termo* into joints (of rabbits) which had been rendered artificially tuberculous, but with most unsatisfactory results. Nor were they more successful, when, in cases of phthisis, they injected it into the veins. These results might have been anticipated, however, from the fact that the *B. termo* is aërobic in its growth and not pathogenic, it can only live in the presence of free oxygen, whilst the *B. tuberculous* flourishes in closed cavities of the body, and seems to shrink and die in pure, dry air. In fact, the value of the dry air and "mountain cure" of phthisis really depends upon the inability of this horrible organism to endure healthy and cleanly conditions. It objects to wholesome surroundings and cold water as strongly as the workhouse tramp and the habitual criminal, and "should be treated accordingly."

Criticism founded on experiments as futile has been offered by Dr. de Toma (*Estudios sobre la tuberculosis*). "He isolated," says the author significantly, "*a* bacillus termo," but did not describe its properties, and cultivated it side by side with that of Koch in various delectable media, such as urine, blood-serum, ascitic fluid, pus and so on. And what may be called these strange bed-fellows seem to have got on very well together—there was food enough for all, so why should they devour one another? And then he came to the conclusion that under the very different lung conditions the result would be the same, and, therefore, the theory and reports of Cautain were alike unworthy of belief! But here we must repeat the happy phrase of Volkmann, in the last Surgical Congress—"Der mensch ist kein Reagensglas."—the human body is not a test tube, when we recall the fact that the *aspergillus niger* cannot be grown in a silver vase, although it does not seem to take up a particle of the metal; it is clear that the slightest change in what lawyers call the *locus in quo* may utterly stultify the most elaborately prepared experiments with bodies so capricious and sensitive as these. Nevertheless, the question of the antagonism of *B. termo* and *B. tuberculosis* is still a doubtful one.

But in another part of the same field, some investigations carried on almost contemporaneously by Emmerich and De Pawlowsky have given admirable experimental results. The former having accidentally noticed that a rabbit, which had been infected with erysipelas of the head, was proof against carbuncle, repeated the injections with several others, with the uniform result that the latter disease had no chance in the conjunction; the prophylaxis was complete. And even when the carbuncle had time given for its development in the unfortunate animal, and cultivations of the bacillus of erysipelas were then injected into the veins, the result was good, for six recovered out of ten so treated; whilst everyone of the rabbits infected with carbuncle and kept as control objects died.

Zagari repeated these experiments with guinea pigs as recipients, but found that the poison of erysipelas only retarded but did not arrest the action of that of carbuncle. But, then, he used attenuated cultivations of the former, and only illustrated the axiom that a retarded force can only act, *cæteris paribus*, as a retardant. But he was able to establish another instance of antagonism by shewing that injections of the virus of scarlatina really rendered the cavys refractory to that of carbuncle.

Chaveau and Toussaint believe that the immunity acquired after a single attack of certain diseases is a natural bacteriotherapy, in the sense that the first attack leaves in the body a product of bacterial life which is fatal to its reappearance. And the outcome of this theory is the injection of fluids which have been sterilized by exhaustion, that is, by growing in them the given germ until it will grow there no longer, filtering the liquid through biscuit porcelain and injecting it as a prophylactic. And this has been practically done in order to protect—and successfully—from swine-fever, typhus, septicæmia, and carbuncle.

How do they act? It will be better to reply, as the señorita did with such ingenuous astonishment when asked who was her father—"Quien sabe!" and the more so as hypothesis is the most unfortunate explanation imaginable in all scientific difficulties. The authors fill half a page with sentences punctuated with alternate notes of interrogation and admiration; we may content ourselves with saying at once, as I have ventured to suggest, and as they do at the end—We do not know. But, from the mass of evidence which has been collected, the doubt applies to the "how," scarcely to the fact.

SUMMARY.

1. The basis of the science of bacteriotherapy is an antagonism which exists between certain if not all bacterii.

2. That a nutritive medium in which our form has lived is inimical to the life of another or to the same organism.

3. The new science assumes two forms: (*a*) Bacterioprophylaxis, (*b*) Bacteriotherapia. The first, the best-known form, and already largely and successfully employed. The second demonstrated experimentally in animals, and which still awaits clinical sanction for use in man.

4. Experiments on the question of the prophylaxis conferred by substances generated by the vital energy of microbes in media in which they have lived, give the key to what may be in certain cases the mechanism of bacteriotherapia, and may foreshadow what it is destined to effect in the future. The problem is excessively difficult because we see that the minutest physico-chemical changes alter the course and the result of the struggle for existence on the bacterial battle-field.

III.—NOTES FROM FRENCH JOURNALS.

By H. R. HATHERLY, M.R.C.S.

Extra Uterine Pregnancy (*Le Progrès Médical*).—M. Terrier, of Bichat, has operated successfully on a case of tubal pregnancy; the diagnosis was easily made. From an operative point of view, tubal pregnancy may be considered a tumour of the fallopian tube, a special salpingitis, not less curable than the other forms. The adhesions of the fœtal cyst were most marked on the side of the placental adhesion. The operation was performed fourteen months after a false labour, which occurred exactly at the ninth month.

Primary Suture of the Bladder after Hypogastric Operation for Stone (*Le Progrès Médical*).—M. Pozzi operated for stone on a patient eighty years of age who was free from cystitis, selecting the high position. Three sets of sutures were inserted, first, catgut sutures to bring together the cut edges of the bladder, the wound having been made as small as possible; a second set of interrupted silk sutures brought together the mucous membrane, and a third set of sutures were used for the skin; a pre-vesical drain tube was used; no permanent catheter was left in the bladder, but the urine was drawn off every three hours. Suture is indicated when the bladder is free from catarrh; it obviates prolonged decubitis and pulmonary congestion in the aged. Aseptic catheterism prevents cystitis.

Creasote in Phthisis (*Le Progrès Médical*).—Creasote, first discovered in 1830 by Reichembach, was at first much prized as a therapeutic agent, but subsequently its use was almost completely abandoned. The difficulty of procuring a pure creasote probably led to this neglect, for often an impure compound of phenic acid, containing no trace of creasote, found its way into commerce instead of the pure drug. The researches of Drs. Bouchard and Guibert have again directed attention to the value of creasote as a therapeutic agent. Professor Bouchard has submitted ninety-three phthisical patients to treatment by creasote. He commences with a dose of three centigrammes daily, which was generally continued without variation during the entire period of treatment. In a few cases the dose was increased to sixty or eighty centigrammes, and even to one gramme. Out of these ninety-three patients, fifty-three received decided benefit from the treatment; whilst twenty-five appeared to be absolutely cured. A large number of practitioners have adopted this mode of treatment, not only in France, but in other countries. Pich, at Coblentz, and Sommerbrodt and Proentzel, at Berlin, have done so on an extensive scale, and the two have published, in 1887, the results of their personal experience. Sommerbrodt has, during the last nine years, submitted every phthisical patient who has applied to him to the creasote treatment; and, as he is a noted specialist, he estimates the number of patients at not less than 5,000. He prefers to administer the remedy in gelatine capsules, containing five centigrammes, each of pure creasote, because this method of administration is more pleasant and reliable. Sommerbrodt orders one capsule the first day, two the second, and then three until the end of the week; the second week he orders four daily; the third week five; and the fourth six. The patient should continue taking six capsule daily for several months. A large number of patients have taken in this manner from 600 to 1,200 capsules, and one patient took as many as 2,000. Very nearly the same treatment is carried out in France, and the results generally correspond with those obtained by Professor Bouchard.

The effects of the treatment are most apparent and rapid in early tuberculosis when there is catarrh of the apex, with induration. At

the end of a fortnight, sometimes earlier, there is diminished expectoration, and cough. After a few days, fever diminishes or subsides, and appetite, strength, and increase of weight soon follow. It is not uncommon to find that, after three weeks' treatment, the night-sweats are arrested. These remarkable effects of creasote in pulmonary affections might be expected, if we admit the beneficial effects of medicinal tar, which contains twenty-five per cent. of creasote.

Creasote, which has proved so successful in phthisis, gives still more rapid and marked results in less serious diseases, such as pulmonary catarrh and chronic bronchitis. According to Professor Bouchard, creasote has a special action on the pulmonary lesion, and Sommerbrodt, of Berlin, is convinced that creasote possesses a truly specific action. These experimenters have employed creasote to the exclusion of all other treatment, in order that its value might be better tested. It is of the utmost importance that there should be no doubt about the purity of the drug; in the Parisian hospitals the drug is chiefly administered in *Clertan's perles*. Each *perle* contains five centigrammes of creasote in etherised solution, enclosed in a thin transparent capsule, which is perfectly soluble. The solvent facilitates the diffusion of the remedy, and its conveyance to the lungs, as it is eliminated by the breath.

Dr. Richelot on the Treatment of Hydatids of the Liver (*L'Union Médicale*).—In 1885 Dr. Richelot first claimed the advantages of making a free incision into the peritoneum over Recamier's method, and the treatment by the large trocar. Notwithstanding the perfection to which Dr. Debove has recently brought the employment of puncture followed by injections of corrosive sublimate (one part in a thousand) Dr. Richelot condemns this plan of treatment in suppurating cysts and in living multiple cysts containing hydatids, but admits that simple puncture is satisfactory in simple cysts, although there is even then a possibility of inflammatory or gangrenous complications. Unfortunately it is often difficult to know whether a cyst is simple or not, although the presence of the tumour may be readily diagnosed, as also its form and size. After evacuation by puncture there will still remain points which are doubtful, and surprises may be frequent, as it is a blindfold sort of treatment. Dr. Richelot, therefore, holds that a free incision into the peritoneum is the best plan, as it allows the cyst to be examined and its nature to be distinguished. A large laparotomy is not always necessary, a small incision often sufficing. If adhesions are found, and the tumour is not very large, it may be only advisable to open it, without attempting its removal. The use of a large trocar is as serious as a small incision; but the latter enables the surgeon to see what he is about, and to evacuate any hydatids, and to completely cleanse the sac. A free incision also allows the removal of any prominent cyst, reaching a cyst when in the substance of the liver, and permits the introduction of such sutures as may be needed. The peritoneum is protected from the escape of fluid, and antiseptic treatment is easily carried out when the cyst has been reduced to a small size.

Dr. Richelot records two cases in which a free incision was necessary for diagnosis. The first case was that of a young woman, æt. twenty, having a tumour, very movable, and apparently not connected with the liver, so that at first it was thought to be a floating kidney, and afterwards a tumour of gall bladder, etc. Dreading the dangers of puncture, Dr. Richelot made a free incision on the 19th April, 1888, and came upon a mass of liver, like a floating supernumerary lobe attached to that organ by a large pedicle. This lobe had formed the tumour. As there seemed to be fluctuation, Dr. Richelot punctured, and hydatid fluid escaped. The cyst included in this lobe was opened, the cyst walls were extracted, and the liver was sutured. The patient recovered rapidly.

The second case was that of a woman, æt. twenty-five years, suffering from a smooth hard tumour, deep seated, and not very movable. The intestine was in front of the tumour, but was easily pushed aside. Diagnosis was very difficult, the disease having lasted twelve years. On the 20th April Dr. Richelot operated. He found a purulent cyst with thickened walls partly embedded in the liver. The wound was closed, and only a slight *cul de sac* remained after the operation. Recovery was rapid. In both these cases a simple puncture would not only have been insufficient, but also dangerous. Incision is the best and only really-curative method of treatment.

Inoculation for Charbon in Russia (*Revue Scientifique*).—During the three years ending 1888 Professor Cienkowspy performed 20,310 inoculations to prevent Charbon in sheep. The average loss was 0.87 per cent. in a flock of 11,000 sheep. The mortality, which had been usually from 8.5 to 10.6 per 100 fell to 0.13 per cent. after inoculation. In his experience, after thirteen months of preventive inoculation, eighteen sheep out of twenty were able to resist the action of the most virulent Charbon. These results are most satisfactory, and should much facilitate the introduction of preventive inoculations into Russian agriculture.

Congress of Hygiene and Demography, 1889 (*L'Union Médicale*).—At this, which is one of the many congresses which will be held at Paris during the exhibition, the following questions will be proposed by the committee for discussion: 1. Measures of administrative order, and medical steps to be adopted in different countries for the protection of health and life in early infancy. 2. The removal and utilisation of solid refuse (dunghills, mud, kitchen refuse, etc.) in town and country. 3. *Regime* and distribution of temperature in the house. 4. Action of the sun on pathogenic germs. 5. Protection of watercourses and subterranean streams from pollution by industrial refuse. 6. The health of seaports. 7. Dangers caused by alimentary substances derived from animals which contain toxic alkaloids. 8. Statistics and causes of death in towns.

Resection of the Rectum for Epithelioma (*Le Progrès Medical*).—Professor Terrier has removed, successfully, at the Hotel Bichat, a circular epithelioma of the rectum situated in the middle third. After the removal of the growth the two cut extremities were brought together by sutures placed in a circular form.

Gerlier's Disease or Paralysing Vertigo (*Le Progrès Médicale*).—Dr. Eperon reports two cases of this curious affection which have come under his notice, presenting, in addition to the ordinary disorder of vision, ptosis, diplopia, temporary obnubilation of sight and well marked ophthalmoscopic lesions. In the first case there was marked hypercœmia of the papillæ; and in the second there was papillary stasis although vision was normal. The general symptoms comprised slight headache and evidence of paresis in the muscles of the forearm. The ptosis and diplopia were both intermittent. Dr. Eperon thinks that the anatomical lesion at the root of Gerlier's disease is a meningeal hypercœmia, especially localised in the occipital, where the known cortical centres of vision of the movements of the eyelids, and probably also of the oculomotor muscles are situated. This hypercœmia is mostly temporary and intermittent, but it may often become permanent enough to react on the circulation of the optic nerves.

Caffeine in Acute Pleurisy (*France Médicale*).—The use of caffeine as a diuretic is commented on by Dr. F. Comby. He administers daily 1.50 grammes each of caffeine and benzoate of soda for a period of twelve days; diuresis results, and the disease disappears in three weeks. Caffeine is an excellent adjunct to milk diet, and is the most powerful and certain diuretic known. It is tolerated in doses of two grammes daily for long periods, provided the kidneys are sound. It is of great value in the last stage of heart disease, when digitatis has become useless. It should always be prescribed in moderately large doses (one to two grammes). Instances of intolerance are rare; the drug is quickly eliminated, and has no cumulative action like digitatis. M. Comby prefers caffeine to convallaria, sparteine, and strophanthus.

Vaccination and Re-vaccination in the French Army (*Revue d'Hygiene et de Police Sanitaire*).—A ministerial order, dated November 20th, 1888, relative to vaccination and re-vaccination in the army, contains an important innovotion; it is, that all soldiers forming the reserve and the territorial army must be vaccinated or re-vaccinated on the occasion of their being called together for exercise. In order not to interfere with military instruction, it has been suggested that the vaccination should only be performed on the eve, or even on the day, of their being disbanded. This innovation is justified by the fact pointed out by Medical Inspector Vallin, that small-pox is almost exclusively limited to the reserve and territorial troops, and that in the event of a general mobilisation of troope the ravages of small-pox would be terrible. During the siege of Paris, small-pox deprived the army of nearly 5000 combatants. In the present day, thanks to better regulations, the army will have a much greater immunity from this, the most preventable of all diseases, and a great step will have been taken towards rendering vaccination more general. The lymph which is to be generally employed is animal lymph, which will be supplied from five centres: Val de Grâce, and the hospitals at the military stations at Chalons, Bordeaux, Algers, and Philippeville.

The Identity of Erysipelas and Acute Lymphangitis.—According to MM. Verneuil and Clado, acute lymphangitis is only another form of erysipelas. Both are contagious, infectious, and parasitic. They are due to a special microbe, which can be readily distinguished and isolated, it may be cultivated, and animals can be inoculated with it. This microbe, which has been so far only discovered and described in erysipelas, is also found in acute lymphangitis, having the same characters and peculiarities. The two diseases ought therefore to be no longer considered distinct.

Dangers of the Treatment of Otorrhœa by Powdered Boracic Acid (*L'Union Médicale*).—It was first pointed out by Schwartze that the routine application of boric acid in cases of discharge from the ear is improper. The cases in which it may be safely employed are

those in which the lower portion of the membrana tympani has a large perforation, in which the the discharge is slight, and mucous membrane is moist. In other cases dry boric acid is either useless or dangerous, especially in acute suppuration of the drum, and chronic suppuration with perforation of Schrappells membrane. These views of Schwartze were fully confirmed at the Berlin Congress in 1886, by Lucœ, Trautmann, Gruber, and Guye, who all confirmed more frequent and severe inflammation of the mastoid apophysis, since dry powders had been applied in aural surgery. The Congress was unanimous in laying down the following rules for the treatment of the ear by any form of powder: 1. Before applying any powdered application, the ear should be thoroughly cleansed and examined carefully. 2. Powder should only be applied when the condition for the evacuation of pus are favourable. 3. Only very small quantities of powder should be insufflated at a time. Amongst the chief causes of the retention of pus are, viscidity of the discharge, narrowness, and unfavourable situation, of the perforation of the membrane, and the presence of any powdered substance in the external meatus.

Sulphate of Eserine in Chorea (*Journal de Médicine de Paris*).—Reiss recommends hypodermic injections of one milligramme of sulphate of eserine twice a day; he asserts that in many cases he has cured patients in from five to six days by this treatment. In the more serious chorea of adults he has not obtained such satisfactory results. He has also obtained satisfactory results from the same treatment in tetanus, paralysis agitans, spinal sclerotis, and in one case of hysteria in a man, a case which was accompanied by a remarkable exaggeration of all reflex movements.

Pilocarpine in Traumatic Tetanus (*Journal de Médicine de Paris*).—Dr. Cassati reports three cases of traumatic tetanus cured by the injection of large doses of chlorhydrate of pilocarpine. He inoculated with tetanus nine rabbits, and thanks to the treatment, all recovered except two. Recovery was rapid, but in every case there was a relapse after the first disappearance of all tetanic symptoms. This relapse always terminated in recovery or death. The symptoms disappeared a few hours after the injection, with the exception of trismus, which continued until recovery. Animals inoculated with tetanus bear doses of pilocarpine which would infallibly destroy healthy animals.

Diabetes (*Journal de Médicine de Pais*).—Dr. Dujardin Beaumetz differs from the views enunciated by Dr. Worms, namely, that diabetes does not shorten life. He has fought against the milk regime, which he considers one of the very worst methods of treating diabetes, he also allows potatoes. Dr. Germain Sée, who was at first doubtful whether normal urine contained sugar, has, in conjunction with Dr. Hardy, shown by experiment that sugar is a normal constituent of urine, as was also proved by Claude Bernard. As regards treatment, Dr. Germain Sée fully agrees with Dr. Beaumetz.

Paralysis Agitans and Revolving Mirrors (*Journal d'Hygiene*).—It is generally admitted that the singular disease first described by Parkinson in 1817, and which is characterised by a rhythmic trembling, which is continuous and progressive, and which, sooner or later, is accompanied by muscular weakness, is most rebellious to all treatment. Until quite recently the prognosis in this disease has always been most unfavourable; whilst therapeutic remedies in paralysis agitans have been futile. The great variety of treatment advocated sufficiently proves how unsatisfactory the results. There is now, therefore, considerable astonishment at the results obtained by Dr. Luys, from the employment of revolving mirrors. On the 22nd March, 1889, Dr. Luys exhibited before the Medical Society of Hospitals, a man, aged forty-four, suffering from typical paralysis agitans. For four years the patient had been unable to carry a glass of water to his lips; he could not button his own clothes, or write, and his speech was hesitating and jerky. Dr. Luys decided to attempt hypnotic treatment, with revolving mirrors. At the fourteenth sitting, the improvement was considerable, the trembling of the hands had so far diminished, that the patient could carry a glass half filled with water to his mouth, although before it had been necessary to place the glass on a chair, and kneel down before it to lap the liquid without touching the glass with his hands. It is interesting to know that a morbid condition of long standing, and supposed to be incurable, can be rapidly and notably improved by the simple physical action of mirrors in rotation, placed before the eyes.

The patient received no hypnotic suggestions during the first few days, and it was only when considerable improvements had been manifested, that rarely some suggestions not to tremble were made. However, the really efficacious action of this treatment reminds us of the strange influence of rapid and successive luminous vibrations at first on the eyes, and then on the nervous centres. This influence was not very marked at the earlier sittings; but accumulating day by day, it finally induced a condition of collapse, coupled with a peculiar sleep, a sleep which might be called mechanical, possessing sedative and therapeutic qualities of a power as yet unknown. But one solitary fact is not sufficient. The case reported by Dr. Luys opens out a new field, and it is to be hoped that further observations will confirm the real power of hypnotic treatment, and give into our hands a new weapon with which to combat a disease, hitherto deemed incurable.

IV.—NOTES FROM RUSSIAN, POLISH, BULGARIAN, AND SWISS JOURNALS.

By VALERIUS IDELSON, M.D., BERNE.

Hydrochlorate of Pilocarpine as a Specific for Hepatogenous Jaundice.—In the Polish monthly *Nowiny Lekarskie*, May, 1889, p. 230, Dr. Wl. Witkowski (pronounced "Vitkovskee"), of Ostrov, writes that hydrochlorate of pilocarpine represents a specific remedy for simple hepatogenous jaundice, except cases of malignant or benign new growths of the liver. He uses the drug hypodermically, in the shape of a two per cent. solution, which he injects a (Pravaz) syringeful once a day in delicate persons, and twice daily in stronger ones. From the fourth or fifth day of the treatment the individual dose is increased to one-and-a-half syringeful. All subjective symptoms (intolerable itching of the skin, hepatic and gastric pain, etc.) are strikingly alleviated even after the very first injection. Catarrh of the stomach, duodenum and biliary ducts and jaundice disappear in from one to three weeks. The most striking results are observed in cases of inveterate severe catarrhal jaundice of several months' standing, in which all ordinary means fail to bring any relief to itching, hepatic colics, and gastric spasms. On the other hand, in such cases where the pilocarpine treatment does not bring about any improvement in the course of from ten to fourteen days, the practitioner can be pretty sure that he has to deal not with simple icterus, but with a case of malignant disease of the liver, as a subsequent course of events will prove. Hence, pilocarpine may be conveniently used as a means for the differential diagnosis. The drug may be resorted to in all cases where the patient's heart is found to be more or less sound. Dr. Witkowski's statements are based on nearly thirty consecutive cases of jaundice treated successfully by the remedy during the last three years. One case—his first one of the kind—is adduced in detail. It refers to a woman of forty-one suffering from severe nephritis complicated with wandering enlarged liver, gall-stones, ascites, œdema of the lower limbs, and recurrent jaundice of four years' standing. The patient had been previously treated more or less unsuccessfully by Carlsbad waters, Priessnitz's compresses, abdominal belt, etc. Pilocarpine was resorted to in the dose of one-sixth of a grain, once or twice daily. The results surpassed all expectations. In three weeks the patient was practically well. The woman enjoys good health ever since (three years have elapsed).

Pigmentation of the Skin from the Internal Use of Arsenic.—In the *Correspondenz Blatt fuer Schweizer Aerzte*, June 1st, 1889, p. 347, Dr. E. Haffter, of Frauenfeld, the editor, draws attention to a peculiar intense dark discoloration of the integuments, which sometimes follows a prolonged internal use of Fowler's solution. He adduces two instructive cases of the kind from his own practice, both of them referring to ladies. One of them, æt. thirty, suffering from some intensely itching, inveterate rash, was treated with the liquor in ascending doses, from five to eight drops, three times daily, for about eighteen months (with occasional short intermissions). During the next three years the lady continued the treatment by herself, without consulting any doctors. When seen again recently by the author her complexion was strikingly dark; while her neck, body and extremities were found to present precisely the same appearance as observed in severe cases of Addison's disease. Any other accessory symptoms, as occasionally produced by arsenic, were absent. The other case refers to a patient of thirty-five, suffering from squamous eczema of the head of many years standing. The solution was ordered in ascending doses, from four to eight drops, three times a day. By the end of four months her face became dark, while her neck and body proved to be studded with "positively astounding pigment deposits." At the same time there were also present such toxic symptoms as nausea, abdominal pain, etc. It is interesting to note that the first patient's sister suffered during her pregnancy from an unusually extensive and intense pigmentation of the skin. Hence the supposition is justified that in the patient's family there might exist an inherited special tendency to pigmentation, determining a high sensitiveness to all agents promoting the formation of pigments in the body. Pointing to cases of the arsenic exanthema described by several British and American authors, Dr. Haffter invites his readers to communicate their own experience concerning the exceedingly unpleasant complication in question.

Calomel as a Diuretic in Dropsies and Exudative Inflammations.—Following the suggestion of Professor D. I. Koshlakoff, Dr. Vladimïr F. Büshüieff, house physician to his clinic (*St. Petersburg Inaugural Dissertation*, 1888, pp. 80), has carried out thirty observations on twenty-six patients in order to determine the value of calomel as a diuretic remedy. The drug was given usually in three-grain doses (with sugar or Dover's powder, in wafers), three times a day, for three or four consecutive days, but sometimes for seven, and once even for twelve. Of twenty-six cases, twenty referred to dropsies (eight of cardiac origin, six of renal, five of hepatic, one of leukæmic) and seven to exudative inflammations (three of pleurisy, two of chronic peritonitis, and one of pericarditis). The outcome of the observations may be briefly summarised as follows: 1. Calomel, given internally in large doses, represents a powerful diuretic means. 2. In a majority of cases the diuretic effects become marked on a third or a fourth day of the administration, and last for three or four days; in some cases for from five to eight, but exceptionally only twenty-four hours. 3. The daily quantity of the urine amounts sometimes to three or four litres (even to 4,350 cub. cc.), but usually is less considerable. 4. The proportion of solid constituents in the urine sometimes increases, but in other cases decreases. 5. The diuretic action of the drug seems to depend upon a stimulating influence on the secretory elements of the kidney, as Fuerbringer has first pointed out. 6. Calomel acts best in anasarca and ascites of cardiac origin. 7. In renal dropsies its action is less pronounced and less constant. 8. In hepatic dropsies it is still less marked than in the preceding cases, and is altogether "capricious." 9. The same holds true in regard to cases of inflammatory effusions. 10. In spite of all usual precautions (washing out the oral cavity with a solution of chlorate of potash, cleansing teeth, etc.), the use of calomel is invariably accompanied by toxic symptoms, which mostly are of a severe character. [As a matter of fact, only in two of 26 cases the accessory effects were limited to a slight tumefaction of the gum and salivation. In ten, moderate stomatitis, with ulceration of the gum and purulent discharge developed; while in 7 there was observed intense stomatitis, with extensive ulceration of the buccal mucous membrane, and enlargement of adjoining lymphatic glands. In every one of the patients the drug gave rise to diarrhœa with three or four, but sometimes with five, seven, and ten stools a day.] 11. In view of the facts, the administration of calomel as a diuretic is justified solely in such cases where all other diuretic means prove inactive, or where a rapid removal of dropsy is indicated more or less urgently. 12. On the whole, as far as the therapeutics of dropsies is concerned, calomel should be relegated to the modest place which it has occupied previously to its coming in fashion. [Professor V. A. Manassein (*Vratch*, 1888, No. 1, p. 12) has also tried calomel as a diuretic in two cases of cardiac disease, and in one of ascites. In all the three patients there developed severe toxic symptoms, which induced him to give up any further administration.]

On the Influence produced by Perspiration on the Gastric Juice and Urine.—In the *Vratch*, No. 20, 1889, p. 455, Dr. Viktorin S. Grüzdeft describes his interesting experiments on seven persons, undertaken in Professor V. A. Manassein's clinic, in order to study the changes in the gastric juice and urine, produced by profuse sweating (the latter was induced either by means of an ordinary hot bath, or by a Russian vapour one, or a "sweating chamber.") The author arrived at the following conclusions: 1. The acidity, digestive power, and total quantity of the gastric juice, as well as the proportion of free hydrochloric acid therein, are distinctly decreased under the influence of perspiration. [The total loss of the bodily weight after sweating varied in individual observations from 120 to 1020 grammes.] 2. The proportion of pepsine, however, remains apparently unchanged. 3. The intensity of the changes is determined (*a*) by the patient's general state [in healthy persons the alterations are less pronounced than in patients suffering from chronic gastric catarrh]; (*b*) by intensity of perspiration [the more intense the perspiration is the more considerable is the decrease of the acidity]; (*c*) by the time elapsing between sweating and secretion of the juice [the longer the interval is, the larger is the decrease.] 4. The alterations occurring in the juice may last from several hours to two days. 5. The acidity of the urine remains unchanged. 6. In view of the facts *sub*, the conclusion is justified that gastric disturbances in phthisis may be caused, to a certain extent, by profuse night sweats; and that gastric affections widely prevailing amongst soldiers may be dependent—at least partially—upon profuse sweating during marches, exercises, etc.

Creasote in Pulmonary Phthisis.—In the Bulgarian bi-weekly, *Meditzinski Preglëd*, 1888, August 30th, p. 89, Dr. Brzezinski (pronounced "Bjezinskee;" a Polish name), of Plevna, details his experience concerning the treatment of pulmonary phthisis by creasote (*creasotum e bitumine fagi*). He lays down the following propositions:—1. Creasote is a very good tonic and antiseptic means, which alleviates cough and expectoration, lowers the temperature, and, before all, improves the patient's general state. 2. To secure satisfactory results, however, it is necessary to use the remedy in large doses for a prolonged period (for many months). 3. The best results from the drug are obtained in incipient phthisis, and in cases free from fever. 4. Patients tolerate the remedy very well. Any unpleasant accessory effects are exceedingly rare, and, when present, depend upon the employment of an impure preparation. 5. Hæmoptysis does not contra-indicate the use of creasote. In the presence of tendency of blood-spitting it is useful to add iodoform. 6. Most conveniently the drug may be administered in the form of pills, after Sommerbrodt's formula which is this:

℞ Creasoti e bitumine fagi ..... 5 grammes.
Balsami tolutani 20.0
Excipientis amari ..... q. s.
Ut f. pill. No. 100.

D.S.—To take one pill on the first day, two on the next, three pills daily for a week, four pills daily for the next week, etc., until nine pills (0.45 of creasote) a day are reached.

Cases of Rudimentary Uterus in Bulgaria.—At a meeting of the Sophia Medical Society, Dr. Shishmanoff has communicated (*Meditzinski Preglëd*, Nos. 13 and 14, December, 1888, p. 224) two cases of arrested development of the womb. One of them refers to a girl of five, in whom "not a trace of the uterus could be detected by any method of examination" (what for the child was subjected to that sort of exploration is not stated). Another case is that of a generally well-developed married lady, aged twenty-two, who had never yet menstruated, though had had some molimina (pelvic pain, etc.) every month. On examination, the womb was found to be exceedingly small (*uterus fœtalis*). A thorough dilatation of the uterine cavity was performed by the author, with the result that a few days later some bleeding occurred. Dr. Shishmanoff, however, is wise enough to state that he is not yet prepared to determine whether the hæmorrhage was a regular menstruation, or simply a metrorrhagia caused by his manipulations.

In the course of a discussion following Dr. Shishmanoff's communication, Drs. Bradel and Molloff stated that they had happened to meet with several instances of rudimentary womb. Dr. Matintcheff related a case of congenital absence of the uterus (the vagina ending in a *cul-de-sac*) accompanied by atrophy of the nipples and areoles. Drs. Khakhanoff, Khristoff, and Mïrkoff adduced each a case of complete absence of the womb, Dr. Mïrkoff's patient being a child with atresia of the vagina.

Quinine and Mercury in Syphilis.—In the Polish weekly, *Gazeta Lekarska*, No. 19, 1889, p. 388, Dr. O. Dymnicki, of Büsk, publishes a very interesting paper on the treatment of syphilis by mercurial inunctions, and a simultaneous internal administration of quinine in the daily dose of from 1 to 1½ grammes. The paper is based on 178 consecutive cases, of which twelve (eight successful, four unsuccessful) are adduced in detail. The main deductions drawn by Dr. Dymnicki forms his elaborate observations may be given here as follows:—1. In a certain, fairly considerable proportion of cases of severe syphilis, the mercurial treatment may be with great advantage supplemented by the internal use of quinine. 2. In such cases, the drug strikingly improves the patient's subjective state and appetite, lowers the temperature, increases the bodily weight, removes salivation and stomatitis, and promotes healing of ulcerations. When the drug is discontinued, all symptoms readily grow worse to improve again as soon as the administration of quinine is resumed. Moreover, the latter allows to increase the dose of mercurial salve. 3. In some cases, however, the administration of quinine is of no use whatever. 4. The drug proves of great service, especially in cases of severe ulcerative syphilis, characterised by considerable oscillations in the temperature, pulse, and, before all, bodily weight, supervening under the influence of the mercurial treatment. In such cases where the oscillations are pronounced comparatively slightly, quinine remains useless. [As a matter of fact, in the eight cases treated by quinine successfully the oscillations in the temperature amounted to from 1.5° to 2.5° C.; in the pulse, to from twenty-six to thirty-six beats per minute; in the body's weight from ten to fifteen pounds. In the unsuccessful cases the respective figures were 0.5° to 1.2° C.; eight to eighteen per minute; three or four pounds.] 5. The former (successful) cases are characterised essentially by an accelerated (*przyspieszona*) systemic metabolism; the latter (unsuccessful) by a retarded (*opieszala*) one. 6. A beneficial action of quinine in the first category seems to be dependent upon its manifesting an inhibitory or retarding influence on the systemic metamorphosis. Hence, the alkaloid strengthens the patient's system and enables it to tolerate larger doses of mercury. 7. In such cases, in which the tissue metabolism is retarded, and which are characterized,

beside but slight oscillations in the bodily weight, etc., by a more or less constant headache (increasing from constipation), considerable enlargement of many lymphatic glands, and by fairly frequent salivation, the mercurial treatment should be supplemented not by quinine, but by some means strongly promoting the systemic metamorphosis.

Another "Pleasant" Mode of taking Castor Oil.—In the St. Petersburg weekly *Meditzïna*, No. 16, 1889, p. 7, Professor Tïmofëi J. Bogomoloff, of Gatchïna, writes that he has succeeded at last to discover a pleasant method of the internal administration of castor oil. The mode is this: he takes one and a half ounce of white gelatine, and dissolves it in cold water, or in cranberry water (*klükvennyi mors*, a favourite sour beverage in Russia.) Then he adds six ounces of castor oil and half an ounce of purest glycerine, and gently heats the mixture until a thick homogenous mass is obtained. The latter is mixed with half an ounce of white sugar, ten drops of *oleum naphae*, and twenty drops of peppermint oil. The whole is then poured out in a shallow mould, and left to congeal. In conclusion, the mass, which has the consistence of a firmish marmalade, is cut into twenty-four tablettes of equal size, containing each exactly two drachms (one teaspoonful) of castor oil. The preparation may be at will used as such, or dissolved in a cupful of hot water. In either of the cases it is said to represent a very pleasant article, most completely disguising the taste and flavour of the oil. In fact, many persons experimented upon could not make out what it might be. The purgative action of the "marmalade" or emulsion (which is very fine) ensues in from two to five hours after the ingestion of a dose. The "marmalade" keeps very well.

Impaction of Vesical Calculus in Infantile Urethra.—In the St. Petersburg weekly *Rüsskaia Meditzïna*, No. 14, 1889, p. 221. Dr. Gëorgy J. Kramarenko, of Ooman, describes the case of a healthy and strong boy, æt. two, who was brought to him on account of retention of the urine, caused by the impaction of a vesical stone in the prostatic portion of the urethra, and vainly treated with catheterisation by other practitioners. On examination, the bladder was found greatly distended, the meatus as well as anterior part of the penis reddened and swollen. The poor child was suffering from incessant agonising tenesms; on straining, only a few drops of the urine escaped. After prolonged attempts (under chloroform), Dr. Kramarenko at last succeeded to pass a metallic catheter into the bladder, and drew out several tumblerfuls of a clear, but highly concentrated urine. The stone, however, could not be pushed in either direction. For a week or so, catheterisation was made twice daily. Ultimately, to relieve the boy's unspeakable suffering, the author extracted the calculus (of the size of a small bean) through a perineal incision, to the left from the raphe. Hæmorrhage was trifling. The wound was plugged with iodoform gauze, and a catheter introduced into the bladder for twenty-four hours. On the next day, the child could freely pass water *per vias naturales*, the lips of the wound having glued together. On the fourth day, fever and purulent discharge from the urethra appeared, which, however, readily yielded to a purgative, and intra-urethral irrigations with a boracic acid lotion. Shortly afterwards, the wound soundly healed. Dr. Kramarenko asserts that cases of impaction of calculi in the urethra occur in reality by far more commonly than they are reported in literature. As a rule, the stones get jammed about the external orifice of the urethra, and sometimes require a bloody dilatation of the latter.

V.—OBSTETRICS AND GYNÆCOLOGY

Does the Menstrual Flow Originate in the Tubes? The Act of Menstruation Viewed from an Inverted Uterus. By E. J. C. Winard (*Gaillard's Med. Jour.*, May, 1888).—Margaret, æt. about thirty years, multipara; occupation a basket weaver; was delivered of a child five months before at term. The placenta was adherent, and the attendant pulled it away, leaving the vagina filled with a mass supposed to be a tumour. When she applied to Dr. H. for treatment, she was much reduced and very nervous. Upon examination the uterus was found to be inverted. Proper treatment was given, and when she was able a reduction was attempted, but failed because the patient refused to take an anæsthetic, and was too feeble to have it done without. She left the place, but returned a few days before my visit. She came to the office complaining of hæmorrhage. It was found that she had been menstruating for four days for the first time in five months, or before the birth of the child, and that she was flowing more freely than was her normal habit; had much pain, nervousness, and prostration. Upon examination I found the diagnosis of inverted uterus to be correct. The left ovary filling Douglas' cul-de-sac, and the right one lodging above the ring formed by the neck of the uterus. The tubes were dragged down, and put on a strain in the sac formed by the peritoneal surface of the inverted uterus. The surface of the tumour was of a dark-red colour, studded with points of a darker hue, and resembled the tongue of a bad case of scarlet fever, without the creamy coating. From this surface no discharges to speak of could be wiped away with cotton; but from the tubes a dark healthy menstrual flow passed out drop by drop, and when the tubes were pressed upon would form a stream for an instant. The openings of the tubes of this inverted uterus were dilated, so as to admit the head of a small uterine sound. With treatment she recovered from this attack, flowing several days longer than usual, and I hope to hear further of the case from observations made at future monthly periods.

A Case of Fibroid Tumour Causing Intestinal Obstruction. By John Homans (*Boston Medical and Surgical Journal*).—The patient had suffered from two attacks of intestinal obstruction, one having been accompanied by stercoraceous vomiting during gestation, spontaneous recovery occurring at both times. The presence of a fibroid tumour posterior to the uterus was recognised, but nothing was done on account of the pregnancy. Soon after delivery, which was normal, a third attack of obstruction occurred, finally causing the death of the patient. At the autopsy the tumour was found to be entirely separate from the uterus, and to be attached firmly to the omentum and intestines, receiving its blood supply entirely through these adhesions, which formed foramina between the viscera and the tumour through which spaces portions of the gut had passed and become constricted. The tumour weighed two pounds and a half, and was of a dumb-bell shape. The exhibitor considered the case one which presented a strong argument against the marriage of women with fibroids, and for the removal by abdominal section of superitoneal uterine tumours.

Pelvic Measurements and their Importance in Obstetric Practice. By H. T. Pershing (*American Journal of Medical Science*).—This study of pelvic measurements seems to have been drawn out by the recent revival of the Cæsarean section. The one thing that the advocates of the improved operation most earnestly insist upon is that it be deliberately chosen beforehand, and that no attempt be made to deliver in any other way. The choice of so serious an operation implies a careful examination of the pelvis before labour begins, or as soon after as possible. As a matter of fact, skilful obstetricians have attended women in confinement, with no apprehension of the case being an unusual one, have tried forceps, turning, and craniotomy in succession, and after the death of the patient, have regretted that Cæsarean section was not resorted to in the beginning. It cannot be doubted that in many such cases a correct or even approximately correct knowledge of the pelvis would often lead to better treatment. In order to form an independent opinion as to the value of such measurements as can be taken during life, the author has recently made careful measurements of ninety dried pelves, found in the various museums of Philadelphia. In this number are included twenty plaster casts made by Tramond, of Paris. The author then discusses the history of pelvic measurements, method of taking these measurements, and the deductions to be drawn from the results. He enters into the full detail of the subject, and presents it in its complete aspect.

On the Prevention of Puerperal Fever. By W. W. Jaggard (*Journal American Medical Association*).—The principles upon which the prevention of puerperal fever depends are few and very simple. As summarised by Crédé, there are only two; they are: (1) prevent, as far as possible, lesions of the genital tract; (2) prevent the infection of the lesions that are inevitable. The extent of the necessary puerperal wound includes the entire area of the endometrium that contributes to the formation of the decidua; the neck of the uterus, particularly the os externum; the vagina, denuded to some degree of its epithelium by the friction of the passage of the child. The puerperal wound, thus marked out, cannot be prevented, but its limitation to these boundaries can be secured, in the large majority of normal cases, by attention to the following precautions. 1. Let the diagnosis of presentation and position, and of the stage of labour be made, as far as possible, by the methods of physical examination of the abdomen. Limit to the minimum the number of examinations *per vaginum*. 2. Let the bag of waters rupture spontaneously. The intact state of the bag of membranes must be preserved for at least two reasons: to secure perfect dilatation of the cervix uteri, and to prevent the access of air and other carriers of infection to the cavum uteri. 3. Preserve the perineum and vulvar orifice. If a laceration does not occur, or if episiotomy is done, unite the rent in the one case, or the incision in the other, immediately on the conclusion of labour. 4. Refrain from digital dilatation of the cervix and exhibition of ergot. 5. Deliver the placenta by Crédé's method. The second principle by which puerperal fever may be prevented is to prevent the infection of the lesions which are inevitable. This infection the author considers may occur in one of two ways: contact infection and indirect infection, or so-called self-infection. The surgeon sterilizes

the field of operation, the immediate environment, and everything that comes in contact with the wound, and the obstetrician acts under the same principles. The sterilization of the hands, instruments, appliances, and napkins, and the parts of the parturient woman are of course insisted upon. The author recommends during the first two days of the puerperium gentle friction of the fundus uteri twice daily, to aid in securing firm contraction and retraction, a practice which originated in Carl Braun's clinic.

The Spirit of the Societies.

ROYAL ACADEMY OF MEDICINE IN IRELAND (Dr. Lombe Atthill, president). **Prolapse Uteri treated by Massage and Pelvic Gymnastics.**—Dr. ALFRED SMITH read notes on the treatment of six cases by Thure Brandt's method of massage and pelvic gymnastics. "The treatment," he said, "of this special disorder consisted of (1) the lifting of the uterus; (2) in massage of the uterus and its ligaments; (3) in forced separation and forced closure of the knees; and (4) in tapaotlement of the lumbar and sacral vertebræ.

CASE I.—Mrs. C——, æt. fifty-four; five children; came to the Rotunda Hospital, January 16th, 1888, suffering from prolapsed uterus. Her health was good up to a year ago, when she began to suffer from pains and a great sinking sensation in the pelvis. This was followed in a short time by the uterus protruding outside the vulva. She never wore instruments. Her youngest child is fifteen, and she is twelve years past the change of life. The anterior and posterior vaginal walls were, on examination, quite dry and parchment-like; the cervix was eroded and weeping; the uterus was nine centimètres long, lying outside the vulva, easily reducible; ovary lying in *post cul de sac*. The treatment consisted of uterine elevation, massage, and pelvic gymnastics. January 17th: slight prolapse of the vaginal walls on coughing. January 18th and 19th: ditto. January 21st: the uterus retroverted to the second bone of the sacrum; no prolapse on coughing; has no pain in sacral region; feels comfortable and firm, with no tendency to prolapse, although suffering from a bad cough. January 23rd: uterus again prolapsed. January 24th: uterus retroverted to the first sacral bone; no prolapse on coughing. January 26th: ditto. January 28th: ditto. February 2nd: uterus has not come down since last day; feels quite strong, and in every way better, except for slight pain in the sacral region; uterus retroverted to the first sacral bone; exhibited patient to Dr. Macan, in surgery; he got her to cough, without any prolapse, even of vaginal walls. February 4th, 5th, and 8th: ditto. February 12th: ditto. August 2nd: patient stayed away contrary to my wishes. I exhibited her to the class. She said her womb had not come down since February 2nd, and she felt quite strong.

Mr. G. SMITH gave the notes of five more cases treated on the same lines, all of which seemed to gain relief by the system; but whether the cures were radical or not cannot be said, as most of them did not return to the hospital again.

Dr. WILLIAM BAGOT said, having seen Dr. Smith's cases, he for sometime practised the method himself with varied success; he thought the failures were due in great part to lack of patience and skill in carrying out the treatment.

Dr. MACAN exhibited a solid ovarian tumour, with microscopic specimens. It was a tolerably-rare specimen. The patient was a woman, æt. sixty-eight. She was sixteen years past the change of life, but had lately been attacked with menorrhagia. He found that she had a retroverted or retroflexed uterus, with a pelvic tumour the size of his closed fist. On a bimanual examination the tumour slipped into the hollow of the sacrum, and it could afterwards be moved up into the pelvis, so that it was evident the pedicle was long. They scraped out the uterus at the hospital, which had the effect of curing the menorrhagia. Afterwards she came to him from time to time, and each time appeared to be losing flesh. Then the tumour became abdominal, and she began to grow uncomfortable. It was still very hard, but quite movable. That day week he removed the tumour, which was about the size of a child's head. There was no difficulty in tying the pedicle. There was one point of moment about the matter. He had been looking at this tumour for two years without interfering with it; and if it should be a carcinoma the case would certainly be sufficient to make them all careful how they left such tumours alone so long without operating at any time when there would be a chance of preventing the disease from spreading.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY (Sir Edward H. Sieveking, M.D., president). **On the Presence of Free Uric Acid in Urine as a Test of the Existence of the Gouty State.**—Dr. ARNOLD SCHETELIZ, of Homburg, proposed a test for gout, founded on the quantity of free crystalline uric acid present in the urine of patients affected with any form of gouty diathesis. This free uric acid, as distinguished from the one combining alkalines in the shape of urates, had the tendency, as was known from the growth of renal calculi, to crystallise out and conglomerate with any other crystalline uric acid already present. The practical demonstration of the quantity present in each case consisted in fully determining the whole quantity of uric acid contained in the patient's urine, and then allowing an equal proportion of urine to pass through a filter charged with uric acid, the "lithic filter." In the case of free uric acid being present, this remained on the filter, while the urates passed through unaffected. The author had analysed fifty-five cases, out of which twenty-eight were pathological, and had found from twenty-five to fifty, and more per cent. of the total uric acid to be in the uncombined crystalline form in the urine of patient's who were either manifestly troubled with some form of uric gout, or had been so previously. It had been even possible for the author—and this was the main object of this communication—to make this test available to distinguish between cases of genuine and spurious gout. This form of uric acid could, by treatment with baths alone, or with alkaline waters, or both combined, be diminished for awhile, but would, in most cases, reaccumulate.

* * * *

CLINICAL SOCIETY OF LONDON (Christopher Heath, F.R.C.S., president). **Sclerema Neonatorum and Œdema Neonatorum.**—Dr. STEPHEN MAKENZIE showed two children, one subject of sclerema neonatorum, and the other of œdema neoatorum. The first infant was six weeks old. Its condition was noticed when three weeks old, but might have existed prior to this period. The affection was most marked over the back and over the loins, extending round to the shoulders on each side, and almost symetrically down the thighs. The second case was a baby only three weeks old. He pointed out that the condition bore much resemblance to the preceding, but it was a distinct affection. He remembered that Dr. Barlow has suggested the possibility of its being due to erysipelas, and the rise in temperature lent some colour to this hypothesis, although its march was not that generally followed by that disease.

Case of Successful Tendon Grafting.—Mr. MAYO ROBSON gave the history of a case of severe injury to the forearm and hand, involving principally the ulnar border. The dorsum of the hand was entirely divested of muscular and tendonous structures, and the palm was extensively lacerated. Wishing to preserve the arm if possible, he took a piece of hanging tendon from the front of the hand, four inches and a half in length, and stitched it to the extensor muscles, and the remaining fragment of the extensor tendon. The wound was kept aseptic, and no sloughing took place. The man had now good movement, and was able to return to his work as a weaver. The hand could be pronated and supinated, and he could move the thumb and index-finger. He had taken a good length of tendon, and had secured it by a single suture at each end.

* * * *

EDINBURGH MEDICO-CHIRURGICAL SOCIETY. **Professor Chiene's Hospital Experience.**—Professor CHIENE read a portion of a paper giving his experience as a hospital surgeon during eleven years. During that period 2,658 cases had been treated in his wards. On 1,600 he had operated; while the remaining 1,580 had not required such interference. He had had 165 deaths. In speaking of the cause of death, Professor Chiene tabulated the results as follows: From blood lesions, seven and a half per cent.; from organismal causes, forty-seven per cent.; from exhaustion, twelve per cent.; from nerve lesions, fourteen per cent.; from shock, nineteen per cent. He gave these statistics in the hope that some improved method, or methods, which would prevent the recurrence of some of such deaths, might be arrived at.

Excision of the Knee Joint for Strumous Diseases.—Mr. A. C. MULLER read a paper in which he made two proposals for the improvement of this operation. To overcome the tendency to redundancy of skin he suggested the removal of an elliptically-shaped portion over the patella and synovial membrane should be removed in one piece. By dissecting the skin to the upper limit of the membrane, and cutting through the films of the rectus and vasti, that could easily be attained. Mr. Muller had performed the modified operation some twenty times with much success.

* * * *

HARVEIAN SOCIETY OF LONDON (Thomas Buzzard, M.D., president). **Enlargement of Thyroid.**—Mr. JACKSON showed a mother and five children, all the subjects of enlarged thyroids. In the case of the mother, Mr. Jackson had removed the isthmus, all the left, and about a third of the right lobe, fixing the remainder of this away from the trachea.

Obituary.

THE LATE PROFESSOR BOYES SMITH.

IT is but little more than a year since the Army Medical School at Netley, suffered such a severe loss by the death of its distinguished professor of hygiene, Dr. de Chaumont; and we now have to record the death of the professor of tropical medicine, David Boyes Smith, M.D., F.R.C.P., which took place on the 3rd June, after an illness of two months' duration.

Dr. Boyes Smith was born in Calcutta in 1833, and was educated in Edinburgh, first at the Academy (where he was a contemporary of de Chaumont's), and afterwards at the University, taking the degree of M.D. and the diploma of L.R.C.S. in 1855. He entered the Indian Medical Service in the same year, his commission being dated November 28th, 1855: served throughout the Indian mutiny, including the siege and capture of Delhi and Lucknow, and many other engagements, amounting in all to fourteen general actions, that is, actions in which all three arms of the service, cavalry, infantry, and artillery were engaged on both sides. He received the medal and two clasps, and was honourably mentioned in despatches. Owing to the hardships undergone in this campaign he suffered from an attack of paralysis shortly afterwards, and for the rest of his life had some loss of power in the left leg.

Having joined the civil branch of the Indian Medical Service, he was appointed civil surgeon at Delhi, and subsequently at other large and important centres in the Bengal presidency, attaining great success in the practice of his profession, and winning the highest opinions from those in authority on account of his great administrative ability. For three years he was Sanitary Commissioner for Bengal; the *Annual Reports* he wrote during this period are volumes full of information laboriously collected, and carefully edited and annotated on all points bearing on the health and sanitation of this province.

Dr. Smith was appointed professor of midwifery at the Calcutta Medical College, and was afterwards, for nearly six years, principal and professor of medicine in the College, and first physician to the College Hospital, receiving repeatedly the thanks of the Government for the successful management of these institutions. In 1882 he retired from the service, and engaged in private practice in Calcutta. On the retirement of Dr. Maclean, in 1885, from the chair of medicine at Netley, Dr. Smith was appointed his successor, and in the same year he was elected Fellow of the Royal College of Physicians of London.

Though a man of wide experience, most extended reading, and great teaching ability, he has not left behind him any systematic work on medicine in any of its departments, though we believe he had the intention of preparing for publication his lectures on tropical diseases. His writings on sanitation and on medical topics are mostly in the form of official reports, and include (in addition to the *Annual Reports* previously mentioned) an account of the *Pilgrimage to Juggernauth*; a report on the *Drainage, Conservancy, and Water Supply of Calcutta*; *on Smallpox, Inoculation, and Vaccination*; on the *Pathology and treatment of Cholera*; and many articles on various subjects in the *Indian Medical Gazette*, which journal he edited for a year.

His fatal illness commenced in the early part of April, with a slight paralytic seizure, though the cerebral lesion must have been in progress long before this. He gradually became worse, the symptoms, however, not being of an ordinary character. Dr. Ferrier saw him in consultation with Sir Wm. Aitken and Dr. Trend, of Southampton, and diagnosed cerebral tumour. The paralysis became more general, and he expired peacefully on the 3rd June.

Dr. Smith was a man of varied attainments and cultivated tastes: he had travelled far and wide, in the Arctic Seas, in China and Japan, America, and all over Europe; he spoke well in public, and his memory was stored with anecdote, so that in private he was a most pleasant companion. His genial and kindly presence will be long remembered by many friends, not only in the medical profession, but throughout the service generally, in India as well as at home. He married shortly after his retirement in 1882, and leaves a widow and one child.

WILLIAM STEWART FALLS, M.D., F.R.C.P., F.K.Q.C.P., M.R.C.S.,

IT is with the deepest regret we have to record the death of William Stewart Falls, who was for upwards of thirty years a resident and eventually the senior physician at Bournemouth. Dr. Falls was taken ill last October with a bad attack of melaena, during which he was seen by Sir William Jenner in conjunction with the local doctors; but he rallied from this attack and commenced work again shortly after, and remained working hard right up to the day of his seizure on May 17th. On the evening of which he was suddenly taken ill with melaena and hæmatemesis, and in spite of everything medical skill could do, he eventually sank on Wednesday, May 22nd. Dr. Falls was born at Clifton in 1825; the son of a naval surgeon, who had seen active service in two actions. He received his medical education at St. George's Hospital, where he was the contemporary of many of the most distinguished members of the profession of the present day. He was house surgeon at St. George's in 1849. Dr. Falls commenced practice in Hampstead with a Mr. Evans, where he remained till 1856, when he went to Bournemouth, which had then an insignificant population of 300, which at the time of his death had risen to 30,000. He took the degree of M.D. at St. Andrew's in 1863; L.R.C.P., London, 1875, and M.R.C.S., England, 1847. He was senior physician of the Sanitorium for Consumption and Diseases of the Chest, Bonrnemouth, and consulting physician at the Royal Hospital at St. Mary's Home for Invalid Ladies, Bournemouth. Dr. Falls took an active part in local matters; and in 1867 was elected a member of the Bournemouth Improvement Commissioners. His kind and affable manner, and his recognised ability as a specialist in diseases of the chest, secured him a large and lucrative practice, and a host of friends by whom his death is sincerely regretted. Dr. Falls in his earlier years was an ardent admirer of aquatic sports, and rowed for the St. George's Hospital Club at Henley, when, with his friend Mr. Coulthard, he won the pairs. His name is honourably mentioned in "Badrumtor" as an oarsman. He was twice married, and leaves a wife and seven children, among whom is Dr. William C. Falls, now practising in London.

Medical Miscellanea.

The subject of our next illustration will be T. Jessop, F.R.C.S., Leeds.

* * * *

Sir Morell Mackenzie has recently been elected an honorary member of the Medical Society of New York.

* * * *

Mr. Michael Carteighe was for the eighth time re-elected President of the Pharmaceutical Society, at the council meeting held on June 5th.

* * * *

The Naval Medical Reserve appears to possess attractions, as some hundreds of applications have been received by the Director-General.

* * * *

Our articles on "Pauperisation by the Hospitals" has been copied into several journals.

* * * *

On May 20th the Workhouse Infirmary Nursing Association held its annual meeting at the Grosvenor Gallery. This Association has done excellent work, and deserves to be widely known.

* * * *

Her Majesty has been pleased to confer a baronetcy on Sir George H. Porter, Senior Surgeon to the Meath Hospital, and one of the Surgeons to the Queen in Ireland.

* * * *

We regret very much to announce the death of Dr. David Boyes Smith, one of the lecturers of Netley Hospital. At the last meeting of the British Medical Association we little anticipated that we should have so soon to chronicle this sad event.

* * * *

We have received from Messrs. Silverlock, Blackfriars-road, London, an excellent little book, entitled, "Medical and Surgical Reference Book," a regular *vade mecum*. It contains information of the most varied character, and is a book which every practitioner should possess.

* * * *

A boy recently died of hydrophobia near Bradford—at least so it was said at the coroner's inquest. Strange to say, the dog which inflicted the bite also appeared at the enquiry, sound and healthy, from which we draw the conclusion that the boy did *not* die of hydrophobia.

* * * *

We were offered the Vice-Presidency of the General Practitioners' Association, an honor which we declined, because we felt sure at the time that there was an object in starting it. What was become of this association? It was intended at the time to help in the return of the list candidates to the General Council. We presume its *raison d'etre* disappeared with their return.

We shall publish in the next number an account of the exhibits interesting in a medical point of view at the Paris exhibition.

* * * *

There is an excellent posthumous paper by the late Milner Fothergill, "On the Moods of the Sane," in our esteemed contemporary *The Alienist and Neurologist*, April, 1889. Dr. Charles Hughes is to be congratulated upon the admirable manner in which the journal is produced, and the high standard it maintains.

* * * *

The Portuguese Government has forbidden public exhibitions of hypnotism on the ground that they are dangerous to the health of both the "subjects and of the spectators, and that the method might be used for criminal purposes"; this prohibition of course does not apply to the therapeutic application of hypnotism by physicians.

* * * *

CASCARA LOZENGES. — Messrs. Richardson, of Leicester, have prepared a lozenge which is wholly free from any taste of the drug. Each lozenge contains two grains of the extract of cascara. It forms a pleasant form of medicine, and is especially suitable for children. In operation these lozenges are adapted to the requirements of adult age.

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the EDITOR, *"The Provincial Medical Journal," Horton House, Halifax.*

Matters of business should be addressed to the Publisher, at the Offices, 10, *Friar Lane, Leicester.*

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked.

Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16*th of the month.*

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

THE STATE OF THE PROFESSION.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—In the numerous articles you have written on the state of the profession you have faithfully depicted its true state, and I regret to find that there is such apathy on the part of those interested. The evils of unlicensed competition, the cutting down of prices or fees, the eagerness with which unpaid appointments are sought for, tell but too surely that the profession is in a bad way. Cannot an association be formed to remedy the evils?— Yours truly,

PHILALETHES.

[☞ There is no use in forming another association. The British Medical Association exists. It is composed of 12,000 members, *most* of whom are general practitioners. It has branches everywhere. If the British Medical Association were to move in this matter, it would soon remedy some of the evils, but it wants putting into action. It is for the members to do this.—EDITOR "P.M.J."]

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—You appear to favour the formation of cheap dispensaries; at least, you do not condemn them in as open language as I think you should use. The cheap shilling dispensaries are the means of bringing down fees, and competition between practitioners is thus rendered keener. Wherever these shilling dispensaries have been established there has been a multiplication of them, to the general injury of other practitioners. Thus Dr. A—— opens one; then Dr. B—— and Co., thinking that they will not be undersold, also open their shilling shops, and so on. I fail to see how you can recognise these institutions, or in any way sanction them. In one of your articles, "a general practitioner" is quoted. His opinion is singular: the shilling fraternity should not be allowed professional support. I do not wish to enter into a personal controversy, so sign myself,—Yours truly,

June 20th, 1889. M.D.

[☞ The writer has not grasped the gist of our articles. The shilling dispensary is but the result of many causes, notably of hospital abuse. We must begin with the free advice given at the hospitals, and with the hospital surgeons. Medical men must live—even by the shilling dispensary. There is no use in beginning reform at the wrong end. It would not be justice to commence with the poorest classes in the profession—the men who are driven by their needs to take up a line of practice which must be felt to be, if not degrading, at least repugnant to professional instincts. We have simply pointed out the causes at work in producing the shilling dipensary.—EDITOR "P.M.J."]

PROPOSED PUBLIC MEDICAL SERVICE OF ENGLAND.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—I would ask you to publish the accompanying proposal for the establishment of a Public Medical Service.

OBJECT.

The providing of medical treatment for those wage earners who are making from 20*s.* to 45*s.* per week for the entire family, on their making small immediate payments of 2*s.* for the first visit and 1*s.* for subsequent visits during the same illness, or 4*s.* per week, paid in advance, for five visits. [Such a scheme would include those in domestic service, shop and factory hands, some clerks, mechanics, and small shopkeepers, these being the classes who generally frequent and overcrowd the out-patient departments of the medical charities. It will not arrange for the providing of medical treatment at the homes of wage earners.]

PROPOSED RULES.

1. That each town or city be divided into as many districts as necessary, a branch being established in each. The rent of the branch to vary from £25 to £45 per annum, and the branch to be situated in the locality in which the patients live.

2. That each branch staff consist of three to six medical practitioners and a dental surgeon. Medical and dental staff to be registered. No unqualified men to be engaged to assist or to act as *locum tenens*. Each practitioner to practise, in so far as he wishes, that branch of his profession which he may select, and to arrange days and hours on which he will treat patients at the branch. Each practitioner to take the fees paid to him by the patient; but in cases of operations, the doctors to arrange beforehand to assist each other, and at a certain division of the fees paid in this case. No practitioner who keeps an open or branch dispensary, or an unqualified assistant, to be eligible to serve on the staff. Practitioners who have resided in the locality for two years to be eligible to serve.

3. The rates and taxes, and other expenses of the branch, to be defrayed by an equal levy on the medical staff, but no expenditure to be incurred without the consent of two-thirds of the staff.

4. That the registered chemists in the vicinity of each branch supply medicine to the patients at the rate of 4*d.* for each prescription, this sum to be paid to the chemist by the patient when the prescription is left to be dispensed. No prescription to be dispensed a second time by the chemist, unless the patient has been advised again by his doctor. Prescriptions to be retained and stamped and dated by the chemist. Standard mixtures, their formulæ to be arranged by the medical staff along with the chemists, to be prescribed, as far as is consistent with the right treatment of the patient. No prescriptions to be copied by the chemist into his books. No drugs to be dispensed by the medical staff, either at the branch or at their homes, to the branch patients. The medical staff not to use any influence with patients, so as to induce them to go to any particular chemist; but each patient to select whom he chooses, or that one who has recommended him to seek advice. Chemists to have the right to refuse to dispense a prescription on more than one occasion, if they believe that the patient so prescribed for is above the 45*s.* "wage limit," and until they discuss the matter with the doctor who has prescribed, and to arrange accordingly. [Such a plan is now carried out by many doctors who have clubs, and by those who act as surgeons to post office officials. It would also save the cost of drugs and dispenser to the service, and by gaining the co-operation of chemists would do away with what is known as "counter prescribing," or "prescribing chemists." The sum paid for drugs at 119 London hospitals in 1885 was £48,974; while at Liverpool, eighteen hospitals spent £6,655.]

5. That the medical staff of each branch possess the right to refuse treatment to any who they know are making over the 45*s.* "wage limit;" and further, that each doctor has the right to remonstrate with his *confrères* when he knows that a patient is receiving treatment who is above the "wage limit." And that each practitioner has the right to tell patients to come to his house in cases where any special examination—as of the eye, ear, or throat, etc.—is required, provided always that the patient is charged the Service fee.

6. That the fee for vaccination with human lymph be 2*s.* 6*d.*, and with calf lymph 3*s.* 6*d.*, including the filling up of certificate. No death certificates to be charged for. Certificates with examination to be 2*s.*, and ordinary sick club certificates 1*s.* No death certificates to be granted unless the patient has been seen within twenty-four hours by the doctor.

7. That registered dental surgeons be asked to co-operate, and that they arrange the days and hours on which they treat patients, and that patients be treated at the dentist's residence. That the scale of immediate payments be: Extractions, one tooth, 2*s.*, and each extra tooth, 6*d.* Extractions under gas, 4*s.*, and each extra tooth, 6*d.* Extractions under ether or chloroform, 12*s.* 6*d.* Stopping with amalgam, 2*s.* per tooth. Stopping with gold, 4*s.* per tooth. Artificial teeth and vulcanite plate, 4*s.* 6*d.*, and every extra tooth, 3*s.* Immediate payments to be made by the patients to the dental surgeon.

8. That the fee for surgical operations performed at the branch—the operations being of the class usually done at the out-patient departments of medical charities—be not less than 10*s.* or more than £1 1*s.* (anæsthetic included), and that this fee do not cover the subsequent visits made for dressings or advice.

9. Patients to have the right to complain to the Branch Committee, and further, to the Central Board. Complaints to be made in writing, and not less than six days after the alleged irregularity.

CONSTITUTION.

A Central Board for each city, or town, to be composed of one medical practitioner, one dental surgeon, and one chemist from each branch—each elected by the Branch Committee—to have supreme control. This Central Board to elect twelve public laymen who take an interest in provident and thrift subjects, these being eligible for re-election each year. The board to hold quarterly and annual meetings. Application to be made by not less than three medical practitioners, not in partnership, to the board when they wish to form a new branch. No one to use the title "Public Medical Service" without the written permission of the Central Board. Each branch to have a committee composed of the medical and dental staff, and a number of chemists equal in number to the medical staff. This committee to meet monthly or quarterly to discuss matters affecting the welfare of the branch, and to elect one doctor, one dentist, and one chemist, to represent the branch on the Central Board. No branches to alter, or add to, any rules passed by the board. Proposed alterations to be sent in six weeks before the annual meeting. No branch to in any way canvass for patients, to distribute handbills, or to have any printed material on the branch other than a small brass plate on the entrance door, with the name of the service and of the branch on it. Each branch to fill up vacancies occurring in the medical and dental staff.

Proposed Form of Patient's Card.—Book to be Cardboard, four inches by three inches. On front page: "Public Medical Service of England;" name of branch and address; name of doctor, and hours; "Always bring this book with you." On back page: List of medical and dental staff, with address and hours of the latter; scale of fees; rules referring to patients. Two inside pages: No.; name and address of patient; names and addresses of chemists; space for prescriptions.

[Each branch may have a man and wife to reside there, the latter to act as matron; these to occupy rent free. It will be easy to obtain the services of a retired midwifery nurse, or a pensioner and his wife.]

HOSPITAL CO-OPERATION WITH THE PUBLIC MEDICAL SERVICE.

It is absolutely necessary for the success of this Service that the authorities of the medical charities co-operate. No connection whatever shall exist between the two in so far as referring patients to the charities for treatment, or using them for teaching purposes is concerned, for the patients of the Service are in no way eligible for charitable relief; and further, no honorary subscriptions or public collections shall be taken up to aid the Service, it being understood that it is entirely self-supporting.

Hospital co-operation must exist, as in no case yet reported has a Pay or Provident Service been known to succeed when it has had to compete against a free hospital at which all classes are treated. The different plans of hospital co-operation have been noticed by me in the *Journal*. The main features of it are:—

That hospital committees meet and fix a "poverty scale," and so decide who are eligible for charitable medical aid. My suggestion is that out-patient treatment be refused when man and wife make over 25s. per week; single man or woman, 20s.; each child of family, 1s. 6d. That no one be refused first treatment, but that second attendances be refused unless the patient has his "card" stamped by an official appointed to inquire into his social circumstances. Each patient to state on a printed form: name; age; address; occupation; name of employer; amount of weekly wage; married or single; number of family; in or out of employment; receipt of outdoor relief.

The social circumstances of the patients may be inquired into by one of two well-known ways: first, by having a waiting-hall inspector, paid and appointed by the hospital, as is done at St. Bartholomew's and the London Hospital; secondly, by using the Manchester system, where each hospital sends a list of patients with their addresses to the Charity Organisation Society, whose inspectors inquire into the social conditions of applicants, and who refuse to stamp the hospital card of the patients if they are making over their "poverty scale," the hospital authorities also refusing further treatment.

It has lately been shown [1] that the abuse rate at the out-patient departments of hospitals—taking the above "poverty scale" as a basis—is about 50 per cent. of the whole. Allowing 5 per cent. of these abuse cases to be above the 45s. wage limit and so able to pay the usual medical fees, 95 per cent. would be eligible for the Public Medical Service. I have lately pointed out [2] that, during 1885, 130 London hospitals treated 1,179,661 out-patients; that eighteen Liverpool hospitals treated 244,831 out-patients; and that twelves Glasgow charities, according to the statement that Dr. J. Erskine,[3] treated 72,217 out-patients treated in only three cities. If 50 per cent. of this total (748,358) were refused treatment at the charities, this would give 710,936 persons for the Public Medical Service, after deducting the above 5 per cent. (37,417) who would be rendered ineligible owing to the 45s. wage limit. Supposing the number refused in thirty other large towns could be added on, can it not readily be seen what a fine service may be created if only there is some combination and organization? Let us see if it be true that the medical profession is incapable of organising.

ABOVE SERVICE NOT COMPLETE AS FAR AS SUPPLYING THE ENTIRE MEDICAL WANTS OF THE WAGE-EARNING CLASSES.

This proposed Public Medical Service does not make any arrangements for providing medical treatment for patients at their homes. It is based on the knowledge that the out-patient departments of our hospitals are overcrowded, and by a class who can have no difficulty in paying small immediate fees, and also on the fact that they are unable to pay the usual medical fees of 3s. 6d. to 5s., and 1s. 8d. for a bottle of medicine. The first statement is shown to be true by the figures given by me in the *Journal* for February 2nd, 1889, where it is stated that the sum paid by patients at seventy-two charities was £36,334. By having a system of small immediate payments, the great expenses of book-keeping, making out of accounts, postage, payment of collector, bad debts, and county court will be prevented, and with the result that wage-earners, by thus reducing the expenses of management, will be able to obtain skilled medical treatment for a smaller fee than they could otherwise.

The Public Medical Service, with hospital co-operation, will therefore provide treatment for those who are sufficiently strong in body to go to the branch. If, however, a scheme is to be as perfect as possible, provision should be made for those who are too ill to leave their homes. This can be done by establishing publicly managed and well-conducted provident societies. Unfortunately, the "provident dispensary" system has never had a fair trial, owing to the wild competition for patients between it and the free hospitals. Moreover, the expenses of a provident dispensary are so great that the small payments made by the members during health and sickness are altogether unable to cover them. Rent and taxes, coal and gas, drugs, printing and stationery, furniture, wages of dispenser and collector, swallow up all the members' payments, and with the result that this provident scheme turns ont to be, in so far as the medical staff is concerned, a charity. Dr. Stewart, of Manchester, in the *Glasgow Medical Journal*, 1884, has given his experience of two years' work in the provident dispensary there, and finds that for 12,096 night and day visits he was paid at the rate of 4.716d. per visit. The skilled mechanic claims over 10d. per hour, and extra pay for work over time! In the *Journal* for January 18th, 1887, I have collected statistics of eighty-eight provident dispensaries, having a membership of 293,720. But these, I find, pay their doctors on an average 4½d. per visit. This "rate of remuneration" is absurd, and, rightly, medical men refuse to sanction such, saying, that if they give their services, they would prefer to present them as a charity, rather

[1] *Journal*, May 25th, 1889. [2] *Ibid*, February 2nd, 1888.
[3] *Glasgow Medical Journal*, 1889.

than allow well-to-do wage-earners to pretend they were paying for what they received. There is really no further necessity for medical men to start another plan of charitable medical relief. The limit of unpaid medical services has, as Dr. Fairlie Clarke said in 1875, been reached, and it is the duty of medical practitioners to avoid being taunted with the statement that, next to the poor-law, their profession is the greatest pauperising agency in the country.

What a pity it is that each young medical practitioner, who "seeing how destitute his neighbourhood is of the means of providing the poor with skilled medical aid, has resolved, with the aid of some Christian friends, to establish a hospital," and so on, had not turned his mind to provident and thrift subjects. May we benefit by the mistakes of the past! Dr. Stewart asks—and we should answer—the very pertinent question, "Is there any virtue in giving an article to a man for less than its real or market value when he is able to pay the full value for it?" In order, therefore, that a provident scheme may be worthy of the name, it must have honorary subscribers—that is, unless the medical staff agree to work for well-to-do people for nothing. Perhaps the plan followed in Germany, where there is compulsory insurance against sickness, accident, and old age, is the best. There the employer is made to pay a sum equal to half the amount paid by the *employé*. There must also be a sliding scale of payments for infants, children, adults, old people, and chronic invalids; while the rule giving a member the right to demand "immediate treatment" by the payment of 5s. or 10s. must be obliterated, it being entirely foreign and most injurious to any insurance scheme. Again, the rule which states that not more than four children of a family are to be charged for, the remainder being treated free—that is, as charity cases—is absurd, as it gives about 13 per cent. of the whole number the right to receive without paying. It is a pity that the provident system had not been started on a fair working basis; but it is to be remembered that it has had to compete against the fearful odds offered by the free hospitals. In principle it is perfect, and no doubt, if the Public Medical Service cannot secure hospital co-operation, it will have to fight against those hospitals which charge from 1d. to 2d. per visit, and will accordingly have to charge similar fees.

I claim, if the above schemes were carried out:

1. That a great strain would be taken off the funds of our medical charities if they ceased to provide medical aid for those who are well able to pay for it. The genuine sick poor would then receive proper attention, instead of, as now, being driven back on the poor-law. The present gross abuses of our hospitals are slowly stifling charitable feelings, and if these go on the public will take as little interest in them as they now do in the parish infirmaries. There is little use in saying that wage-earners as a body are unable to pay the small fees of a public medical service, for even in the East End of London, Mr. C. Booth has lately shown that out of its population of 908,958, 577,000, or 65 per cent., "are classes in comfort and rising to affluence."

2. That the tone and manly feelings of wage-earners would be increased, and that they will be encouraged in the way of self-help and self-respect. These feelings are being gradually undermined owing to poor-law, medical charities, and other forms of relief, while the degradation of character due to this feeling of dependence on the charity of others is working enormous evil. No doubt many wage-earners hold that it is the duty of their employers to provide them with medical treatment and medicine; hence, not looking on this provision of aid as a charity, but as a right, no feelings of gratitude are created. When free treatment is given to all at the hospitals, then the greatest excessive to frugality, sobriety, and independence are withdrawn. I think it is no exaggeration to say that on the happiness, welfare, and contentment of the wage-earning classes of England depend, to a great extent, the prosperity of this country. There is, or should be, in every one of us a feeling which perhaps may be described as the "necessity of providing," and the person who either actively or passively hinders the progress of this incentive, either for the purpose of bringing himself into prominence or notoriety, or for the purpose of keeping down the working classes, is an enemy. Christian almsgiving is a religious duty, but only when the recipient is worthy of relief. When given to others it works evil, for it is found in all instances that pauperism, or a dependence on the frugality and work of others, increases in direct proportion to the funds provided for the indolent. The statistics of our medical charities show, like those of the poor-law, that this dependence of the wager-earner on the charity of others is largely a preventable disease. Perhaps when some *soi-disant* philanthropist succeeds in demoralising and debasing the wage-earners, by doling out just as much charity as brings the givers into notoriety, to a low level of servility and dependence, the public will put a stop to what might be termed "trading in hospitals." The demand for charitable aid by the well-to-do is mainly due to the encouragement it receives—it grows by what it feeds on. This is an unpleasant fact, but it had better be grasped at once. A short time ago a guardian asked a man who was making 52s. a week, but who was spending all he had, "What will you do when old age comes?" "I'll do as my father did—go to the workhouse." "I'll go to the hospital" seems to be the outcome of the present-day teaching.

3. The happy and old-fashioned doctrine of "live and let live" among the public, medical practitioners, and chemists would be encouraged. It is useless for the wage-earner to say that because he gives his penny for his bottle of medicine, or drops it into the hospital Saturday box, he is paying for what he gets, while all the time he does not pay the doctor who treats him at the hospital. He is, therefore, a pure charity case in so far as the doctor is concerned. This point cannot be too prominently dwelt upon, more especially as the wage-earner now often says, "I pay for what I receive." It is well that the demands now made upon the services of doctors are far too great, and that the average payment for services is too small. If a public medical service had anything to do with true medical charity, one would not speak on this subjects of payments. Further, it may be said, perhaps, that this service is for the benefit of doctors. Well, if it be so, why deny it? Do merchants and other business men not combine together to offer their services for a certain sum, only with this very great difference, that members of the medical profession try to make their charges harmonise with the social conditions of the patients?

No doubt the above proposals will meet with some opposition, but this will just be the amount of resistance required to call forth a little extra exertion on the part of its sympathisers. A final acceptance must take place, else the springs of charity will be dried up. I would appeal to those of the clergy who advocate the virtue of giving to impress on their hearers that it is no charity to provide the well-to-do with that which they can easily obtain by their own efforts and at their own expense, but to tell them that it is not right of them to steal the funds provided for the aid of the poor.

A large and ever-growing number of medical men are determined that the time has come when an effort must be made. Sir Spencer Wells, Sir Charles Trevelyan, Messrs. T. Holmes, Fairlie Clarke, Ernest Hart, and Ogle, the Charity Organisation Society, and many others, have given their best time and attention to constructing a plan by which skilled treatment may be provided for the wage-earning classes. It is to be hoped that the young generation may prove themselves capable of carrying out many of their suggestions, and show that they are able and willing to take their place in discussing and carrying out a plan which, if thoroughly worked, must reflect credit on the profession, and at the same time—by relieving our medical charities of the treating of a class of the community far above the scope of charity—to make room for the promised poor, while they help to raise the wage-earner into a more independent position. Besides, the daily Press has now come to our aid, and has plainly said that a Royal Commission is urgently needed to inquire into the present disorganised condition of the hospitals. A number of practitioners acting on hospital staffs will oppose all efforts to restrict the giving of charity to all, as they hope that, the pay-system being introduced, they will receive wages for work done by them. But in Birmingham, at the General Hospital, where four assistant doctors are paid £400 among them, £5,000 are made out of the patients they treat at the charity by selling tickets at 3s. 6d. each, these giving six weeks' treatment to each well-to-do pauper. Thus the very low fees made in practice are vastly higher than those paid to the hospital staff.

Again, may I be permitted to say that is not a charity proposal, and, therefore, business-like remarks are alone called for. Another class will oppose this scheme. Some time ago a merchant said to me: "You see, our workers are paid from 30s. to 37s. per week. It is most essential that they work regularly, and, therefore, it is in my interest that the men are healthy; and, further, that when ill they receive medical aid. These men say it is my duty to provide doctors for them. I do this in the cheapest way, namely, by giving half a sovereign to Hospital Sunday Fund, or by sending a donation to a hospital. If the doctors choose to treat these men, who are well able to pay, as charity cases, that is not my business, but theirs. I deal in the cheapest market." This is an honest statement, and represents the feelings of more than half who subscribe.

If the medical profession do not wake up, and show the public that they are quite capable of forming and developing a scheme by which the working classes may obtain "fair treatment for a fair fee," then one of two things are likely to happen. Either the co-operative societies will step in—as has been done in Canada, Shanghai—or pass a law compelling medical men to give their services for a fixed fee.—Yours truly,

Liverpool, June 22nd, 1889. ROBERT RENTOUL.

THE ELECTION AT THE ROYAL COLLEGE OF SURGEONS.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—In offering myself as a candidate for a seat in the Council of the Royal College of Surgeons of England, I do so as an independent fellow, aware that there is a strong feeling in the profession that the provincial members of Council are too few; and not one of those few lives in this part of the country.

I consider that both Fellows and Members need to have a bond of interest in, and of union with, the college, beyond the fact of their possessing diplomas, and that this would be obtained if the Council were to submit their Annual Report to a general meeting for consideration before adoption, and if they also convened a meeting of Fellows and Members to consider any heavy expenditure or other matter of great importance. The College of Physicians and the College of Surgeons are working together, and I think it would be well if, as is the custom at the former, the president were elected by the annual meeting of Fellows at the latter. The question of admission of Members on the Council I have read, conversed, and thought much about, and conscientiously feel that had I remained a Member I should not have felt any claim to the position. I believe that many Members do not desire it, and am satisfied that any who aspire to the Fellowship, now that admission to it is practically reduced to passing a good examination, and paying a moderate fee, can well, even if in heavy practice, prepare and pass by energy. This I say from experience, as I, when in hard work, passed both examinations in one week.

The Fellows were created to be the Electors and Council of the college. Those first elected without examination were prominent surgeons to large hospitals, having been raised to that position by their professional brethren and fellow citizens. The rest have the guarantee of possessing the highest surgical qualification in the world. All Fellows are Members, therefore have the welfare of the Members at heart, and it is well that all advantages of Fellowship should be upheld, as an inducement to many who are now Members, and we regret do not join us, to take the higher qualification. Also, I am opposed to both draft bills for Parliament. The first seeks to throw the Council, with the offices of president and vice-president, free to Fellows and Members as one body. The second by its wording "not less than six shall be Members" practically does the same.

If I am honoured by being elected to a seat on the Council, as representing my brethren in the provinces, and having their and all other Fellow's interest at heart, I shall feel it alike a pleasure and a duty to attend the meetings regularly.—I am, Sir, faithfully yours,

Clifton. CHARLES STEELE,

Late Surgeon and Consulting Surgeon to the Bristol Hospital for Sick Children; late Senior Surgeon to the Bristol Royal Infirmary; late Lecturer at the Bristol Medical School.

Bibliographical Record.

BOOKS, PAMPHLETS, ETC., RECEIVED.

Our Portrait Gallery.

T. R. JESSOP, F.R.C.S.

THE history of the Leeds School of Medicine has yet to be written; its name has been identified for nearly a generation with the progress of surgery, and its best traditions have fortunately been preserved, so that as a school of medicine it now stands in an unrivalled position. The public spirit of the inhabitants of Leeds has always stood to the profession, hence the Leeds medical charities have been well supported. The School of Medicine has been for some years connected with the Yorkshire College, and now it is one of the affiliated Colleges of the Victoria University; the student, therefore, who enters as a pupil at Leeds can proceed to the degree of M.D. Victoria University—the difficulty so far as the M.D. qualification is thus removed. The surgical fame of the Leeds Infirmary has been well sustained, and those who know Mr. Jessop and his surgical work will willingly admit that he is worthy of a place with Hey, Teale, and the other surgical worthies who have made the school famous.

Mr. Jessop was born at Brighouse in 1837; he was educated at the well-known school at Giggleswick, which was then under the direction of Dr. Butterton, assisted by Mr. Howson, father of the well-known Dean of that name. Like many other eminent surgeons, our subject commenced his professional education in the old-fashioned way—viz., by a five years' apprenticeship, half of which he spent with Mr. Robert Farrar, of Brighouse (now of Scarborough); half with the late Mr. T. Nunneley, of Leeds. After this sound training he entered in 1856 as a student at the Leeds School of Medicine. At that time the lecturers in the school were Dr. Chadwick, Messrs. T. P. Teale, William Hey, Samuel Smith, Samuel Hey, all of whom are now dead, After qualifying as a Fellow of the Royal College of Surgeons, England, in 1860, he was elected Resident Medical Officer to the Leeds Infirmary, a position which he held for five years, and which he resigned in 1865 to commence practice in Leeds. He was at once admitted to the School of Medicine as Demonstrator of Anatomy. A year later he was chosen Lecturer on Physiology, and Surgeon to the Leeds Public Dispensary. On the decease of his former master, T. Nunneley, in 1870, he was elected Surgeon to the Leeds General Infirmary; and owing to the retirement of Messrs. Wheelhouse and Teale a few years ago, he is now the Senior Surgeon. On his election as Surgeon to the Leeds Infirmary he resigned his appointment to the Leeds Public Dispensary, and was transferred to the Chair of Surgery. On the amalgamation of the Yorkshire College with the Victoria University, he became the first Professor of Surgery; but owing to increasing professional calls, he was obliged to resign this appointment. It is not to be wondered at that with such a training Mr. Jessop should have at once started with an extensive general and consulting surgical practice. A five years' apprenticeship, four years as a student, five years as a resident medical officer, represent fourteen years of student life.

This fact in the life history of Mr. Jessop may be usefully taken into account by some of our younger aspirants for professional position. During the early portion of his career Mr. Jessop was Surgeon to the Great Northern Railway Company. This appointment brought him very prominently forward as a witness in railway compensation cases, work in which he still frequently engages. One of the judges at the assizes complimented the profession at Leeds on the evidence given by the Leeds surgeons as being eminently fair, and as not exhibiting that partisan character which but too frequently marked expert testimony in other towns. Mr. Jessop has not been a voluminous writer, though he has published a number of valuable papers, chiefly on surgical subjects.

Mr. Jessop has been President of the Yorkshire Branch of the British Medical Association, and now represents the branch on the Council. He was deservedly chosen President of the Surgical Section, August meeting, 1889, at Leeds.

Original Communications.

THE ANALOGY OF CHOLERA AND SUMMER DIARRHŒA.

By Sir William Moore, K.C.I.E., Q.H.P.,
late surgeon-general with the government of bombay.

Diarrhœa, according to standard authors, may be accompanied by all the symptoms of cholera, except rice-water stools and suppression of urine. But cholera often commences as diarrhœa, and subsequently developes into cholera. It is often impossible to define whether the attack should be called cholera or diarrhœa. Summer diarrhœa is induced, if not by heat, at least during the season of the greatest heat. In hot summers there is a good deal of diarrhœa, in cold summers little. Summer diarrhœa is therefore most common in cities, for cities are warmest. In America some practitioners regard heat-stroke and summer diarrhœa as one and the same, just as in years past cholera in India was regarded by some as a form of insolation, or more recently as a form of thermic fever not developed into insolation. Dr. Ballard having recently investigated the cause of summer diarrhœa, finds that it does not begin until an earth thermometer, at least four feet deep in the ground, shows 56°, and that diarrhœa prevails so long as the earth temperature is at this point, irrespective of what the external temperature may be. It is also stated that the lighter the soil the more the diarrhœa. Further, Dr. Ballard has expressed a provisional opinion that the essential cause of summer diarrhœa resides ordinarily in the upper layers of the earth, where it is intimately associated with the life process of some micro-organism. In this connection Pettenkofer's cholera theory will be recollected. Pettenkofer's conditions are a certain amount of moisture in the ground, indicated by the sinking of the ground water, a porous ground, and a certain amount of organic matter in the ground for the nutrition of the germ. Summer diarrhœa is sometimes characterised, like cholera, by cramps, and the affection in children assumes the likeness of cholera to such an extent as to be called *cholera infantum*. Moreover, when cholera prevails, diarrhœa prevails, a legitimate inference being that both conditions must be due to similar agencies. And, as mentioned before, diarrhœa often becomes cholera, raising the unanswerable question, "At what precise stage do the sufferers from diarrhœa become cholera stricken?" To regard the case as cholera, only when certain symptoms supervene, is not consistent with the fact of so many cases commencing as diarrhœa and terminating as cholera. And it is not in accord with what is admitted with regard to various other maladies—diphtheria for example—of which there are very mild and very severe instances. Greater or lesser severity of diseases, is not sufficient for regarding them as essentially different in their nature. But it has become the custom to esteem cholera as a disease marked by certain signs only, and when it spreads epidemically; and to say a malady is not cholera when all these symptoms are not present, and when it does not spread. The variability of type and of symptoms in other diseases is fully recognised, and the same breadth of view should be accorded to cholera.

In the mortality reports, the term simple cholera generally begins to present in the summer. Now the diagnosis of a typical case of cholera from a typical case of diarrhœa is sufficiently easy. But the diagnosis of this so-called simple cholera or summer cholera is not always easy. If we refer to standard authors on the subject, we find after a detail of the symptoms of cholera, under summer diarrhœa, in "Quain's Dictionary," "But the fluids from the stomach and bowels are rarely free from bile, and are not so like rice water as in true cholera." On this it may be remarked that the symptoms of true cholera vary as much as the symptoms of any disease. Cholera has been described under at least thirty different terms, called into use by the varying nature of the malady, for two cholera epidemics rarely present exactly similar phases. And cholera has been characterised by so many peculiar and anomalous symptoms as almost to justify the thirty different terms. Ziemssen says, "It is impossible to distinguish the one from the other (cholera from diarrhœa), unless regard be had to the absence or prevalence of cholera." Flint, the American author, writes, "It is by no means easy to distinguish the first case of *cholera nostras*." In "Reynolds' Medicine" it is stated, "In some of the worst forms of the English disease the complaint would be at once recognised as real cholera, if it occurred during an epidemic." Roberts says, "The symptoms resemble those of true cholera, but ordinarily they are less severe."

The pathology of diarrhœa, as investigated by Dr. Klein, closely assimilates to that of cholera. . . The intestines are found empty, or containing only fluid, with follicular ulceration, congested spots, denudation of epithelium, and degenerative kidney changes. Again, not only the symptoms, but also the *sequelæ*, of summer diarrhœa resemble those of cholera, especially with reference to a low febrile condition which may result after both maladies.

Many have been accustomed to regard cholera as a disease unknown in the East before 1817, and unknown in Europe before 1832. There is, however, incontrovertible evidence that cholera existed in Eastern countries long before 1817, for the Portuguese met with it when they first went to India centuries previously. And as regards it having existed in Europe, the fact has been elaborately shown by Macpherson in his "Annals of Cholera." It is true that some of the writings on which reliance is placed, both in Europe and in the East, to prove the antiquity of the disease, do not always describe the malady as marked by suppression of urine, rice-water stools, and collapse. But this is only in accordance with the numerous variations of the disease as noted above.

Now, a consideration of the above, and of other points for which there is not space, connected with the two maladies, leads to the conclusion that summer diarrhœa is in reality a phase of cholera. Thus, while the latter prevails most in the hot season of warm climates, the former is most prevalent in the hot summers of temperate climates. Both have been recently attributed to micro-organisms, having their *habitat* in the earth. Many cases commence as diarrhœa, and terminate as cholera. The diagnosis is sometimes so uncertain that we are told by competent authority that it must depend on the presence or absence of cholera. Cholera is a disease which assumes many phases, one of the most usual being diarrhœa. The pathology of the two conditions is very similar, the *sequelæ* are identical. Lastly, it can be shown that cholera is not a new disease in Europe, but has always prevailed. There is no necessity for persons to be scared if it is asserted that summer diarrhœa is in reality a phase of cholera, differing only from the Asiatic type in degree; for we ought to be prepared to meet cholera in its more insidious forms, one of which is diarrhœa. And the best treatment for cholera is the best treatment for summer diarrhœa, both medical and sanitary.

ON THE COMPARATIVE ANTISEPTIC VALUES OF CHLORIDES, NITRATES, SULPHATES, AND OTHER CHEMICAL SUBSTANCES.

By C. T. Kingzett, F.I.C., F.C.S.

In the winter of 1887 I wrote a paper on the comparative antiseptic values of chlorides, nitrates, and sulphates, and since then, and contributory to the main investigation which is still in progress, occasion arose to repeat many of the earlier observations, and to test other substances. In the earlier stage of the investigation, the comparative antiseptic value of the several substances were determined in respect of two standard mixtures—viz., extract of beef and flour paste. As, however, the results were mutually confirmative, there was no occasion to employ in the later observations more than one standard, for which extract of beef was chosen. In reviewing the results to which reference was made, several medical papers commented upon the fact that putrefactive agencies were alone examined, and in one case this was coupled with an expression of regret that specific micro-organisms isolated from all others, and known or assumed to be the direct or indirect cause of specific diseases, were not studied. In reference to this, I may state that such experiments were not required for the purpose I had in view. Moreover, not only is it very difficult to obtain such specimens, but, as a matter of fact, the prohibitive effects of various chemical agents are more or less general in character in the sense that, as they act in relation to any one micro-organism so they do to others, for instance, by destroying them or so altering the composition of the medium that it becomes either incapable of sustaining the life or development of the respective species.

It is now generally taken for granted that micro-organisms do not of themselves give rise to disease, but that under favourable circumstances, that is to say, by development in suitable media, they lead to the formation of certain chemical products which are noxious in character and behave as poisons to the human organism. This is the view I have consistently taken since I have interested myself in such subjects, and I am glad to know that, while when first propagated it was held up to a good deal of scorn, it is now universally accepted.

If, then, this view be correct, it is not improbable that the same or allied poisons may be elaborated or produced through several distinct agencies, that is by different micro-organisms or from varying media; and if it can be shown that antiseptics act uniformly as a class in prohibiting the processes of chemical change or fermentation by which such poisonous products arise, the experiments which I have already described, in common with those about to be referred to, are truly comparative in character, and the results are reliable for guidance in dealing with sanitary matters and the prevention of disease.

That antiseptic agents act more or less uniformly, and are to that extent comparable, is borne out by the fact that the processes for the inhibition of which they are applied are also uniform. Writing broadly, it is fair to state that most processes of fermentation or chemical change, induced by micro-organic life, depend upon two chemical acts, the one hydration and the other oxidation; that is to say, more or less complex molecules like albumen are split up into a certain number of simpler bodies, and oxidation of these, or of some of them, proceeds simultaneously or subsequently. It is not improbable that the more active poisons are produced when the chemical changes are mainly hydrolitic in character. For instance, tyrotoxicon (a substance which Victor C. Vaughan claims to have identified chemically as diazobenzol) is said to be produced by inoculating ordinary milk with the butyric ferment and keeping the mixture in a closely-stoppered vessel for some eight days.

As further bearing on these views it may be noted that in the course of some observations made by Dr. Burdon Sanderson, F.R.S., upon the results of an experimental investigation carried on by Dr. Klein and Mr. Lingard, he characterised them as affording "solid ground for the anticipation that whatever means may be found effectual as prophylactics against septic infection, will also be effectual *in so far as they are applicable*, against tuberculosis."

In commenting upon the same researches, Dr. George Buchanan carried the argument farther, and found "one noteworthy point vouched for by Dr. Klein"—viz., "that when it is possible to recognise, as in the case of anthrax, tubercle, and swine-fever, the minute organisms that play an essential part in the disease, and to compare them with other and similar organisms which are not so much infective as putrefactive, it is found that chemical agencies which are wanting in destructive effect upon the putrefactive organism, have a power, often when present in extremely minute quantity, of arresting or destroying the life of the infective organism."

In order to bring the later results of my observations into general accordance with the former ones, I deemed it advisable to repeat the whole of the tests originally made with chlorides, nitrates, and sulphates in respect of extract of beef. For this purpose, 5lbs. of lean fresh beef was minced and then digested with water at a temperature under 40°C. for three hours, after which the extract was made up to 4 litres, and when cold was strained several times through fine muslin, to remove undissolved portions and solidified fat. In each observation 95 cc. of this extract was taken, and to it was added 5 cc. of the particular antiseptic solution to be tested. These antiseptic solutions, except where otherwise noted, were of 5 per cent. strength; but in cases where the substances were not perfectly soluble, the solutions containing the undissolved particles in suspension were used. The series of experiments first to be described were commenced on November 19th, 1887, and the following table will show the respective days on which the several mixtures became putrid.

SUMMARY OF RESULTS. SERIES D.

Chlorides.

On the fourth day, the mixtures containing the following chlorides had become putrid: Chlorides of potassium, sodium, ammonium, barium, strontium, calcium, and magnesium, as also the standard extract. On the ninth day, the chlorides of iron, lead, zinc, and tin. On the fifteenth day, chloride of aluminium. The mixtures containing the chlorides of copper and mercury remained intact.

Nitrates.

On the fourth day, the nitrates of potassium, sodium, ammonium, barium, strontium, calcium, magnesium, and iron. On the sixth day, nitrate of zinc. On the ninth day, nitrate of lead. The mixtures containing the nitrates of copper and mercury alone remain intact.

Sulphates.

On the fourth day, the sulphates of potassium, sodium, ammonium, iron, and manganese. On the fifth day, sulphate

of zinc. On the eleventh day, sulphate of aluminium. The mixtures containing the sulphates of copper and mercury alone remained intact during the whole period of observation—viz., sixteen days.

It may be noted that, as a rule, as the mixtures became putrid, the colour changed from a dull, dirty red, to bright scarlet, a change probably associated with the initiation of oxidation by the agency of aerobic micro-organisms.

The next set of observations were made in February of 1888, using a similar beef extract (containing 1.796 grms. per cent. of total solid constituents dry at 100°C.) with some selected chlorides, nitrates, and sulphates, and the following other substances:—5 cc. of a saturated solution of "Salufer" (Thomson's fluo-silicate of sodium). 5 cc., 10 cc., 15 cc., and 20 cc. of ordinary "Sanitas" fluid of commerce. 5 cc. Kingzett's Mercuric "Bactericide" (that is a solution containing 5 per cent. mercuric chloride in 5 volume peroxide of hydrogen).

The mixtures broke down in the following order:—On the third day, the standard solution was putrid. On the fifth day, the sulphate of zinc and nitrate of lead mixtures. On the sixth day, the 5 per cent. "Sanitas" mixture. On the seventh day, the chlorides of lead and tin mixtures. On the eighth day, the "Salufer" and sulphate of aluminium mixtures, but mould had appeared on the "Salufer" mixture on the fifth day. On the twelfth day, nitrate of mercury and chlorides of iron and aluminium mixtures. On the fifteenth day, chloride of zinc mixture.

In this series it will be observed that nitrate of mercury broke down on the twelfth day, thus confirming the general evidence adduced by the earlier series of experiments, that this salt is not so reliable as either the chloride or the sulphate. The mixtures containing 10 cc. "Sanitas" and upwards remained quite free from putrefactive change collaterally with the mixtures containing "Bactericide" and the chlorides and sulphates of copper and mercury during the whole period of observation—viz., thirty-four days. These results give this information concerning the antiseptic value of "Sanitas" fluid: that 10 cc. of this reagent is equal in effect with 5 cc. of a five per cent. solution of mercuric chloride.

The remaining series of observations were made with solutions of peroxides of hydrogen of so-called five-volume strength, having dissolved therein five per cent. of the following respectively:—Potassium hydrate (caustic potash), potassium chlorate, bisulphate of potash, borax, borax neutralised with boric acid, sodium benzoate, ethylic ether, glacial acetic acid, quinine disulphate, quinine sulphate dissolved in a slight excess of sulphuric acid, chloroform, phenol (absolute carbolic acid), chloral, pure hydrochloric acid, oxalic acid, boric acid, and sulpho-phenic acid.

On the second and third days the standard extracts broke down in all cases; so also did the sodium benzoate and neutral borax mixtures. On the third day the ether and caustic potash mixtures. On the forth day the quinine disulphate mixture. On the fifth day the potassic chlorate mixture. On the seventh the chloroform mixture. On the tenth day the borax mixture. On the thirteenth day the boric mixture and the mixture containing quinine sulphate dissolved in an excess of sulphuric acid. On the seventeenth day the mixture containing bisulphate of potassium. On the ninteenth day the acetic acid mixture. On the twenty-fourth day the chloral and oxalic acid mixtures. On the twenty-seventh day the sulpho-phenic acid mixture. After thirty-nine days the following mixtures were still good—hydrochloric acid and phenol.

In dealing with these results it must be borne in mind that all the test solutions contained peroxide of hydrogen, which exhibits a considerable antiseptic property, so that the comparative results of the experiments present the specific additional values, so to speak, of the dissolved substance. Of course, the tests, in common with the previous series, were somewhat severe, *as they only give the antiseptic values of 5 cc. of per cent. solutions when diluted twenty times.*

One of the most interesting facts elicited by this inquiry is the pronounced antiseptic value of chloral, which may henceforth find, therefore, an extended use in the domain of medical practice. Only somewhat less pronounced is the antiseptic character of potassium bisulphate. Again, sulphate of quinine, if administered together with sulphuric acid, may be expected, not only to act as a tonic, but also to produce an antiseptic state of the human body. It is interesting also to observe that borax is much more effective than when neutralised with boric acid, notwithstanding that that substance has a higher antiseptic value than borax. Of the other pronounced antiseptics, phenol is, of course, well known, but its application is limited on account of its dangerous character. The influence of the acid reaction is significant, acetic, oxalic, sulpho-phenic, and hydrochloric acids exhibiting very marked antiseptic action.

Acetic acid has been known for ages to be a good antiseptic, whilst hydrochloric and other mineral acids formed the subject of study by Dr. John Dougall, and were found to be powerful antiseptics and disinfectants. Unfortunately they are much too corrosive to be of extended use, either in the household or for medical applications.

Sulpho-phenic acid in common with phenylacetic and phenylpropionic acids, is strongly antiseptic in character, but in the human organism it would probably yield phenol and thus exhibit toxic effects. As regards sulphuric acid (the influence of which is perhaps seen in the results of the observations made with quinine sulphate dissolved in it, and with bisulphate of potassium) it may be remarked that Mr. J. P. Laws has made some interesting observations concerning the restraining and killing power of that substance, both of which he found to be considerable. The antiseptic properties of chloroform water have been studied by E. Salkowski, but in the form of an alcoholic solution (as used in my experiments) they do not appear at any rate to be so pronounced as those of borax.

Respecting "Salufer," an aqueous saturated solution of it, is seen to rank about equally with 5 per cent. solutions of sulphate of aluminium and the chlorides of lead and tin, but this shows the statement made by Dr. Conrad Berens, of Philadelphia, to the effect that it is more efficient than corrosive sublimate in preventing decompositions, to be very exaggerated.

As a matter of fact, experience so far seems to point to corrosive sublimate as to the most powerful antiseptic yet discovered. Klein takes this view, while Koch claims that a solution of 1 in 5,000 can be relied upon for perfect disinfection, since it suffices, according to him, to annihilate all life in micro-organisms and their germs within a few minutes. Klein, I think, rightly regards this statement as an exaggeration of its powers, but there is no doubt of the effects of somewhat stronger solutions. Unfortunately, the terribly poisonous nature of the substance disqualifies it for use except by medical men. Useful as corrosive sublimate

is in the practice of medicine and surgery, it is, however, deficient in one respect, that is power of oxidation. It is capable of killing germs and spores, but has no power of oxidation over the toxic products which may exist in association with them, and this is the more important because these products give rise to the toxic effects which are witnessed in many diseases; in fact, they constitute the real infectants. I have therefore introduced a compound solution of this substance with peroxide of hydrogen and also a number of other solutions, all containing peroxide of hydrogen and definite percentages of various antiseptics under the name of "Kingzett's Bactericides." The preparation of these fluids has involved me, not merely in this and the preceding investigation of a similar character, but also in another study which is not yet completed.

In conclusion, I may perhaps be permitted to make one remark concerning "Sanitas" fluid, and indeed, it is only fair that I should insist upon its great value as a disinfectant for popular and medical use, being wholly innoxious and thoroughly reliable, it having been shown that 10 cc. is equal in antiseptic effect to half that quantity of a 5 per cent. solution of perchloride of mercury, and in addition it is a powerful oxidant.

With respect to the comparative antiseptic values of the better known chlorides, nitrates, and sulphates, the results generally confirm my earlier ones, but the chlorides of aluminium appear to have a somewhat higher value than that formerly assigned to them. It may be said by way of summary that the chlorides, nitrates, and sulphates of the alkalies have slight antiseptic effects, and those of the alkaline earths are not much better. The compounds of manganese, zinc, tin, iron, lead, and aluminium are all of value. As a rule the chlorides are to be preferred. The compounds of copper and mercury are comparatively most effective; the nitrate of mercury is, however, not so reliable as the chloride, which is the most active antiseptic amongst these substances.

The general results will, I hope, be of service in this way, among others, that when a so-called new disinfectant or antiseptic preparation is submitted to the public, directly the composition is known, the approximate value may be ascertained by reference. For instance, so-called kamphorkalk is said to be a mixture of the chlorides of sodium and calcium with a sprinkling of camphor, and it cannot, therefore, be assumed to have a much higher antiseptic value than the chlorides alone, and that is of the weakest character from the comparative point of view indicated in my observations.

FOOD AND DRINK.

By E. Bonavia, M.D., etc.

(*Continued from p.* 398.)

Mr. H. M. Stanley, in his book on the "Congo," vol. ii., pp. 282—296, after giving one of the most frequent causes of fever—a chill[1]—gives what he considers the best kind of food for the Congo region. "Let there be a variety of fresh animal food; well-cooked beef, mutton, game, fish and fowl, with vegetables, etc., etc. . . . Even although other externals are not quite perfect, good food will better enable one to live and withstand the troubles of climatic change than bad food. But about 'beer' I differ. The English beers are too bilious for Africa, and the German beers are not absolutely necessary, so long as red and white wines, clarets and madeiras are obtainable." . . . And he strongly recommends that wine should not be taken during sunlight. "To drink little wine is excellent advice, but I am not yet prepared to admit that total abstinence from wine is better than temperance, either in Africa, or in Europe." My native assistant told me that he found alcohol (native spirits) one of the most efficient remedies in pneumonia among the natives, both immediately after the acute stage, and during weakness after recovery. I believe that a large proportion of the natives of India, who are put down by the "*chowkidâr*," as having died of fever, are cases of pneumonia, natives being very subject to this form of chill at certain seasons, especially if their standard of health is lowered.

The medical officer of one of the Indian railways, who has much experience of European drivers and guards, informed me that he did not think in the least that teetotalers were any less subject to fever than their moderate drinking brethren. He said, "I have one man here who 'lushes' whenever he can. He *never* gets fever. I have lots of moderate fellows, too, whose ailment never is fever." He also said, "I do not think one bit that 'teetotalers' get over fever more readily than others. They never have the bottom that one seems to have who occasionally takes his glass, but you will understand that, from the nature of the railway service, we have *no drunkards*—it is instant dismissal."

I was once told the story of a young doctor in the Indian Medical Service, a total abstainer, who had a bad attack of fever shortly after going to India. He recovered from the fever, but could not get over the weakness it left behind. His friends urged him to take some stimulant, but he resisted until one day he gave in and took a "peg." He afterwards said that he had no idea before of the value of alcohol, to help one out of the debility left by fever. Of course, these are hearsay facts. Another total abstainer, an engineer, found that in India it was impossible for him to do his work efficiently without something to compensate for the absence of alcohol, so he took to the habitual use of large doses of quinine. This drug, however, when taken in excess, irritates the nervous system, I think, more than alcohol in excess; and as to coffee, I think one is readily made angry at things after taking coffee, which he would probably *laugh at* under the influence of a moderate dose of alcohol.

Dr. E. T. Tibbits, in his "Medical Fashions in the Nineteenth Century," says of alcohol: "For my own part I cannot help feeling that, when employed with discretion in definite quantities, it is one of the most useful and energetic therapeutic agents we possess, and for which no adequate substitute has yet been discovered." Shortly after the capture of Lucknow in 1858, I had under my charge more than a dozen Sepoys, all suffering from large unhealthy ulcers on their lower limbs. I tried every remedy for many days, and so did the field surgeon, but without any visible effect. I then gave each a measure of rum, diluted with water, morning and evening. Within a fortnight, many of the sores had almost healed, and the others were in a healthy condition, and healing rapidly.

In the *Pioneer* (an Indian paper) of the 24th June, 1885, Mr. T. Thornton Macklin, medical officer of the East Indian Railway, says that he has had experience of the Arctic and equatorial regions, and has been over the far

[1] My own experience in India confirms Mr. Stanley's statement—viz., that a *chill* is one of the most frequent causes of *ague*. This is also a *faith* with Dr. Law in Eastern Africa.

west and the nearer east. He has experimented with alcohol on himself, and on others. He says he was five years a total abstainer, and has been for rather less than a quarter of a century a *legitimate user* of alcohol. Regarding this drug, he has come to the following conclusion: (*a*) Under no circumstances ought alcohol to be taken in early morning, or even during the day. But it may be used with much benefit and comfort in small quantities, under almost any circumstances, after sundown, and the labours of the day are over. (*b*) Alcohol should not be taken if about to undergo any physical exertion, and especially if unusually great, either night or day. But it is advantageous after prolonged and sustained exertion, either in heat or cold, if about to rest for the night, and in cold countries, if there is proper protection from further exposure. (*c*) Alcohol should not be taken if about to be exposed to extremes of temperature, either cold or heat, whether actively or passively engaged. But it can be taken at any time almost, after exposure to extremes of temperature. Mr. Thornton Macklin speaks of ordinary healthy men. He has repeatedly known cases where no food could be taken without a stimulant. This is a sensible view of the advantages and disadvantages of alcohol. It is evidently derived from actual experience in various parts of the world, of the effects of alcohol, both on the writer himself, and on others.

My own belief regarding alcohol, which has grown up from experience, conversation, and reading, is the following: I do not think there is anyone more offensive than a drunken person, or more unsatisfactory than one addicted to excess in drink. Excess, even when the person does not become what is called tipsy, is very harmful, although exceptions occur in which persons drink largely, and live to an old age, without much apparent harm. I have seen several persons, who, although never drunk, habitually took alcohol in excess. Among these I have seen four or five cases of "alcoholic paraplegia," that is, total paralysis of the lower extremities. Death in all these cases followed not long afterwards. I believe that in cold regions it may be dispensed with, but that in warm climates it is beneficial, both in health and sickness. In Cassel's "Family Magazine" for July, 1888, "Scientific Temperance," p. 461, Dr. Benjamin Ward Richardson is reported to have stated that alcohol "unquestionably lowered the temperature of the body." This may perhaps be the reason why the use of it is of advantage in tropical climates. My experience is that in hot climates, taken in moderation, it is indispensable for steady, efficient, and interesting work in health, and for recovering from the prostration ensuing from fever and other diseases; that even in hot climates, I think less of it is required in winter than in summer. It is not, as has been supposed, only a question of pleasure and enjoyment in the act of drinking, and in feeling toned up afterwards. It appears to be a far more important question—viz., that of health, energy, and intellectual efficiency *next day*. No doubt all important acts in the progress of life have become associated with a feeling of "pleasure and enjoyment."

I have been informed that railway officials, guards, drivers, etc., in India, who are not "teetotalers," do their work more efficiently and satisfactorily than abstainers. Many Europeans in India will say that, during the hot weather, they cannot touch their dinner till they have taken a stimulant. My own experience corroborates this. Even children in the hot weather, in the plains, lose their appetite, and a teaspoonful of whisky or brandy in a tumblerful of water, taken with their food, enables them to enjoy their food. Dr. Parkes made careful experiments with alcohol at Netley. He came to the conclusion that a certain dose of alcohol, taken in a diluted state, increases the appetite. It does so probably by arousing the action of the nervous centres, and, through the means of their telegraphic communications, setting the glands and other feeding apparata at work. It is very probable that just *before* any sustained muscular exertion, taking alcohol is a disadvantage; but taking it in moderation at the end of the day's work, is far from being injurious. I think it recuperates the system and recharges it for both mental and muscular exertions for *the next day*. But it is especially as an *intellectual developer and sustainer*, that I think it of importance. If, however, a person has not sufficient control over his actions, the best thing for *him*, and those who depend on him, is to become a "total abstainer." I believe that, taken in moderation, alcohol is one of the greatest gifts God has given to man. It is not improbable that, in spite of all the miseries (and what step in man's progress has been free from miseries?) brought on by ignorant persons, and those who misuse it, alcohol is inseparable from the civilisation of man, and from his mental progress. In some shape or other it appears to be in universal use where not kept down by religious custom or law. It is now sufficiently proved that the people of Europe owed their culture to the more ancient civilsation of Assyria. Not only this, but it is now even asserted that China owed what culture it had to importations from Assyria. Assyria and Babylonia then appear to have been the "cradle" of human civilisation (or at all events *one* of its cradles).

It is therefore interesting to note that the cradle of human culture was also the place where the *vine* was so common, that it was almost *indigenous*, so much so, that Assyrian artists used it entwined round another of their very useful trees—the date-palm—as a motive for wall decorations in their palaces and temples, and symbolized both in their *Sacred Tree*. It may perhaps have been unavoidable that man may have had to pass through a period of drunkenness before he came to learn the right use of this implement of civilisation. But it is, I think, a hopeful thing that the laws of nature are adequate to weed out, in course of time, all those, who from stupidity, misuse alcohol, and leave the course free to those only who have sense and forethought enough to use rightly this wonderful agent. In health, I know no better calmer of the day's troubles, and no better awakener of the intellect to the wonders of creation, when used in moderate and diluted doses. In disease, there is probably no drug so efficient and so useful in re-establishing health. In all cases, as with other drugs, it should be used with care.

We have been told over and over again, that for the soldier the best thing is *total abstinence*. But in war time *total* efficiency must be taken into consideration—in battle, in camp, in marches, in defeat, in time of sickness, etc. That army is the most efficient, it would seem, which gains the greatest number of successes, with the least loss of life, whether by the bullets and sabres of the enemy, or by disease. No one perhaps would assert that during the Peninsular war the British soldier was the model of sobriety, yet this is what Napier is stated to have recorded of him:[2] "That the British soldier is more robust than the soldier of any other nation can scarcely be doubted by those who,

[2] *St. James' Budget*, November 15th, 1884, p. 13.

in 1815, observed his powerful frame distinguished among the united arms of Europe; and notwithstanding his habitual excess of drinking, he sustains fatigue, and wet, and extremes of cold and heat, with incredible vigour, when completely disciplined; and three years are required to accomplish this. His port is lofty, and his movements free; the whole world cannot produce a nobler specimen of military bearing!"

Then in the words of Boorde,[3] although beer engenders gross humours, "it maketh a man strong—strong and solid of wit, of sinews, of nerves, of temper, as hardly any other food or drink shall make him. All the wine-drinking peoples have always had the better of the water-drinking; all the beer-drinking peoples (who have had the wit to drink what good wine they could get likewise) have had the better of the merely wine-drinking." Then with regard to seamen, I can only say that an officer of the P. and O. Co. told me that the Italian sailors they employed on the Mediterranean lines were efficient and sober, and that the quartermasters were smart men. They *all* had their daily allowance of wine. That it is possible for a nation to make use of wine daily with their food, without exceeding, is amply proved by the Italians. An American missionary in Rome once told me that he never thought of speaking against the use of wine, because he had never met with a case of drunkenness. I believe that ennui and *want of sufficient sleep* have a great deal to do with creating a craving for liquor, in order to restore the balance. Excepting cases of inherited habit, which may or may not have been induced by ancestral irregular habits, the above appear to me the main causes of drunkenness. It has been said, omnibus drivers and conductors, in London, are sometimes worked for sixteen hours. In addition to this excess of work, in winter they have to counterbalance the low external temperation. If the tale of their excessive labour is true, it is no wonder that they are obliged to tipple at frequent intervals, and that their terminus is usually a public house. The question is, does excessive labour lead to the habit of drinking? Even if you fully fed a horse, could you overwork him without plying him with stimulants? On one occasion in India, in the hottest weather, when it blows a scorching hot wind, I was requested to report upon the state of an engine-driver. At one of the previous stations, while the train was waiting, he had fallen asleep on his engine. I made a careful examination, and enquired into the number of hours he was obliged to work: he was working over-time. I reported that the man was in a fit state to take the train on, and that, owing to the number of hours he was obliged to work, I thought it impossible for him to do that work at that season without drinking more than usual. Competition drives men to work over-time, and this, I believe, drives them to drink. Remedy exhaustion by overwork and want of sleep, and I believe you will, to a very large extent, remove the craving for excessive alcoholic drinking.

In the olden times in India, Europeans consumed alcoholic drinks much more largely, and this I think was undoubtedly due to ennui. Then they had no post, no railways, no amusements, and nothing to read. In the "Echoes from old Calcutta," by H. E. Bousteed, p. 143, it is stated that Macaulay thus wrote of Calcutta: "Let me assure you that banishment is no light matter; no person can judge of it who has not experienced it. A complete revolution in all the habits of life; an estrangement from almost every old friend and acquaintance. All this is to me at least very trying. There is no temptation of wealth or power which could induce me to go through it again. We have our share of the miseries of life in this country. We are annually baked four months, boiled four more, and allowed the remaining four to get cool, if we can. Insects and undertakers are the only living creatures which seem to enjoy the climate." Philip Francis, member of council, on the same page says: "Whenever I am worth a clear entire sum of forty thousand pounds, secure in England, Bengal may take care of itself. No, not for that fortune, would I spend the same two years again." On the next page, this member of council uses far stronger language. The ennui in India in those days must have been frightful. Things have much improved since then. Telegraphs, regular and frequent posts, railways, newspapers, books, accessibility to cooler climates, etc., have made a great difference in life in India. With a large proportion of the ennui, a good deal of the excessive consumption of alcohol has also passed away. Alas! there is coming to the front a new trouble—the want of *means* to keep up with the civilisation of the period.

With regard to want of sleep, the effect with some is this: The head next morning feels like a balloon, with no power for work, or for fixing one's thought upon anything, and the craving for food and drink is great. The only effect of eating and drinking more than usual in such cases is solely to feel *better*. It takes two whole days of eating and drinking, and two whole nights of undisturbed rest, to restore the nervous equilibrium. But in the first day, after a sleepless night, it would seem as if no amount of eating and drinking would suffice. Whether all persons who do not get enough of sleep drink more next day is impossible to say. That would probably depend a good deal on constitution, state of health, season, climate, etc.

It might be supposed that a small dose of alcohol, taken diluted, would make one hotter in a hot climate, but this is not so. A mild "brandy and soda," or other similar stimulant, taken after coming in from the heat and worry of the work of the day in the hot weather, not only calms the nervous system and the action of the heart, but *cools* the body. About this I feel no doubt. All those who speak and write against the horrors of drunkenness are doing a good work. Nevertheless, the great advantages which moderate and definite doses of alcohol, properly diluted, produce, more especially in hot climates, appear to be beyond cavil. It is stated that some of the best work done at athletic sports has been done by teetotalers; and that in Arctic explorations it has been found that the advantage to total abstainers is great. But surely all the work of the world does not consist only of Arctic explorations and athletic sports.

Tea and coffee may be very useful in their way, but there are certain prominent facts in the world which cannot be made to suit the ideas of total abstainers. The Chinese have used tea from time immemorial, but it has not been shown that they had no need of opium also, and the importations of this drug into China, and the amount the Chinese grow, may probably be an indication of the amount of dissatisfaction which the average human system has to tea *alone*. The Russians are great tea drinkers, but they are also notorious for the amount of "*vodki*" they consume. All over Europe tea, coffee, or cocoa, is used, but the people have not for that reason ceased to want alcohol also. The Turks, Egyptians, and Arabs, are great coffee drinkers, but with that stimulant alone they have

[3] *Saturday Review*, January 22nd, 1887, p. 120.

not done much. Wherever we turn, we find that neither tea nor coffee are equal alone to keep a nation in the front ranks of progress, and, therefore, it would appear that alcohol is essential to enable a people to keep their place among civilised nations, or to push themselves forward and reach a favourable position there. The "Book of Health," before-mentioned, states, "that some of the best shots at Wimbledon have been teetotalers, and Dr. Carver, whose shooting is probably unrivalled, has never tasted a drop of alcohol in his life." To this may be opposed the following statement: It is said that Prince Bismarck, in his youth, "was able to shoot better and drink deeper than any man in the province." Busch has also told us that the Prince, in later days, indulged in combination draughts of champagne and beer. Yet he is among the foremost in Europe, if not *the* foremost. Certainly this does not prove that he is great because he used to drink deeply, but it does prove that alcohol has not *prevented* him from becoming great, and it has to be shown that he would have had an equal chance of becoming great had he been a "*teetotaler*."

It would appear that different people are suited to different places, and the places suited to them. In one place man can live on beef and water alone (perhaps because he can get nothing else), and ride from before sunrise till after sunset, and tire twelve vegetarian feeders; and this in a climate which alternates between freezing and burning heat. In arctic regions, people may be better off by dispensing with alcohol altogether, that is, in a region where the causes of death are numerous, it is better not to add that of cooling one's blood by opening the capillaries of the skin by means of alcohol. In one place, within the tropics, men can eat a variety of animal and vegetable matters, and take a good deal of alcohol, and yet become athletes, with 150lbs. weight, with five feet in height; while others can live on a mixed diet, drink a lot of "vodki," and reside in a tract of territory, which is now and then almost Arctic in the severity of its winter, and still astonish the world with their tenacity, energy, and perseverance. All this can be done, not only without harm, but with advantage. Change the conditions, and probably that mode of life will no longer be suitable. The great point, however, which appears to have been missed is this, that Europeans have invaded a large portion of the world, are invading more, and will probably end by occupying most of it. In the progress of civilisation, their functions will have to be almost omnipotent, and their brain omniscient. They will have to keep in mind the history of the past, and endeavour to foresee the future, and devise things accordingly, in order to keep their place in the race of life. All they have done has been by the help of alcohol (that is to say not without it), and it has to be shown yet whether they would be equal to this infinite variety of functions on a vegetable diet alone without alcohol. In the human struggle for existence supremacy is not attained by those who waste their time in getting up a multiplicity of "fads," and who distract and divide a nation by extensive experiments on it; but by those who have learnt from the past, who can foresee the future, who have energy, perseverance, and a passion for work of all kinds; and above all, by those who may have sense enough always to show a united bold front, and never to give the slightest advantage to competitors, by always keeping their eyes open to their own interests.

The conclusion I have come to about the use of meat, vegetables, and alcohol, by reading, questioning, and observing, is, that vegetables *alone* can give muscle, energy, and endurance, as in the horse, camel, elephant, etc.; that excluding alcohol, a purely meat diet gives far more energy, endurance, and pluck, than a purely vegetable one; that a mixed diet admits of the combination of both qualities in *one* person, and gives him, therefore, a greater range of efficient work and power in the struggle with competitors; that in the multiplicity of functions which civilised man is called upon to perform, a mixed diet, with many variations, and with the *addition* of alcohol, appears to give him the best chance, not only of maintaining his vigour, his pluck, and his endurance, but of superadding tenacity, a passion for work, and a dogged perseverance, so as to enable him to almost expunge from his dictionary the word *impossible*.

The kind of diet which has brought man to his present stage, moreover, admits of his expanding his intellectual vision almost without limit, and thus increasing his intellectual faculties. By its means the British have reached the first ranks of the human race, and they will be wise if they endeavour to *stay there*. We have, all over the world, seen what it means to be *conquered*. If any nation is silly enough to throw away the advantages God has given it, it then becomes a matter of sentiment, uninfluenced by either historical, or accurate knowledge. That the British, however, could have invaded half the world, have stayed there, and multiplied there on turnips and water, or such weak and primitive diet, is a thing I see no reason to believe.

ON A VISIT TO BIRMINGHAM AND TO MR. LAWSON TAIT.[1]

By J. Milne Chapman, M.D., M.R.C.S.,
Medical Attendant to the Northern Infirmary, Inverness, N.B.

As I had the advantage during February of seeing Mr. Tait at work for a fortnight, and of enjoying frequent opportunities of personal communication with him, I have thought that an account of the time so spent might be of interest to the members of our society, and perhaps might not be without profit. In the first place I may warn those, who like myself, may be anxious to see Tait at work, that it is no very easy matter to do so, at least it does not appear to be, though I am quite sure that he will specially welcome anyone coming to him from the North of Scotland where he himself first saw ordinary medical practice. He is a Scotchman, heart, and soul, and delighted to talk to me of his experience while acting as *locum-tenens* and assistant to Dr. Soutar, of Golspie. He receives very numerous applications from practitioners anxious to see him operate, but as the bulk of his work is private and is undertaken in ordinary sized bedrooms, it is impossible for him to gratify them all. On one occasion one of our transatlantic cousins presented himself, watch in hand, in Mr. Tait's consulting room about mid-day and thus addressed him: "How do you do; glad to make your acquaintance; I'm Dr. So-and-so, from so-and-so, in such and such a State; I've come over in the *Etruria*. We got into Liverpool this morning, and I'm going on the fast cars to London at four o'clock, and I'd like to see you do one or two sections." This, of course, is an extreme case, but the applications were so numerous, not only to see one operation but to be allowed to see 20, 30, 40, and 100 cases, that Mr. Tait felt compelled to institute a system of pupilage which is now in operation.

[1] Part of a paper read before the Inverness Medical Society, March, 1889.

He receives four post graduate pupils for periods of six months at a fee of 100 guineas. For this they are privileged to see all operations in the same way that I was, and which I shall presently describe, and also, two at a time, they attend with him when he sees his hospital out-patients on Mondays and Thursdays. This seems a heavy fee for such advantages, but there is no doubt that it is a good speculation for his pupils, and he has many more applications than he can comply with. Those who have already passed through the system and are now at work in America and elsewhere, have, one and all, succeeded in speedily establishing for themselves positions and practices which they could never have attained otherwise. America is an enormous country and possesses numerous large cities, and therefore, openings for such specialists as are thus trained. On my first presenting myself to Mr. Tait on the day of my arrival in Birmingham, he took me to his secretary's room and instructed her to send me word of when operations were to take place, and I was told there was to be one that afternoon at 2-30. At that hour I accordingly returned to the house, and was shown into a small drawing-room in the hospital wing where I was presently joined by his pupils. After waiting a little, a nurse opened the door and we all trooped upstairs into a small bedroom, with white painted wooden floor and strips of carpet. Resting with its lower end against the window sill was a narrow operating table on which lay the patient already anæsthetised. Mr. Tait in shirt sleeves and holding a small knife between his lips, was standing by the patient's side. No greetings were exchanged even by look, nor was a word spoken. One of the pupils rapidly washed his hands and took up his position opposite as assistant. This post, however, is almost purely a sinecure, as Mr. Tait does practically everything himself. The making of the abdominal incision was the work of less than sixty seconds, and what particularly struck me was the way in which he handled his knife. Never in all my experience have I seen anyone make a knife cut like he does. The instrument is a narrow bladed short scalpel, and he lays it down so that the whole length of the blade cuts. The effect is like that of cutting butter with a good table knife. You hardly notice any motion, but the tissues separate in front of the knife, and the incision is made down in many instances to the peritoneum. One or two touches at most make the wound even from end to end, and then he picks up the peritoneum in two pairs of pressure forceps, and cuts it straight down between them, the assistant meanwhile holding one of the two pairs, these are then removed, he runs his knife up and down the peritoneum and the abdomen is open, actually in a shorter time than it has taken me to read this description, and with a neatness and dexterity which I fear no words of mine can fully convey. The case I speak of was one of fibroid tumour, in size about that of a four months' pregnancy. Mr. Tait rapidly enlarged the incision up and down by putting the tissues on the strain with two fingers in the abdomen and running his knife inside the abdomen edge upwards, the whole wall splitting with as much apparent ease as do the leaves of a book before a good paper cutter. He inserted his hand behind the tumour and worked about for a time. As there was nothing to see of the operation for the moment, I turned my attention on the operator's face. It is a curious face, as those who have seen it will readily admit, long and large featured in every respect, except the mouth, which is unusually small with thin firmly compressed lips. A heavy band of hair—which is long and black and glossy—hung down over the forehead and eye, but what then particularly impressed me was the rigid concentration expressed on every line and feature. The eyes were turned upwards to the corner of the window, but were evidently looking at nothing. Presently he said "Trocar," and a long curved one being handed to him, he took it in his right hand and pulled the point back till it was within the canula, and slipped the instrument down in front of the left hand which was still within the abdomen. Having settled its position, he held it secure with his fingers on the canula shield, and having with the thumb slid the trocar forward, he pushed the instrument still deeper, and on withdrawing the trocar there gushed out about a pint of thick offensive pus. He then said that there was the same condition on the other side, and asked for the aspirator, but meanwhile continued to work away at the sac from which the pus had come, and presently brought it to the surface, a hugely dilated Fallopian tube of the right side. He tied the pedicle in the Staffordshire knot and removed it. He then went to work on the other side, but the sac burst, and he simply squeezed the pus out, fished the sac to the surface and ligatured it straight away. He then brought a third mass up from behind the uterus, oval, and as large as a breakfast roll, which turned out to be a dermoid cyst of the right ovary. The pedicle of this was secured in the same way. At the time he gave this third mass not a moment's consideration but laid it aside, proceeding to wash out the abdomen, using three large pailfuls, about the size of stable buckets, of warm water, running through an ovariotomy tube and trocar. During the process of washing out, he moved the contents of the pelvis and the intestines freely about with the left hand to secure their being thoroughly cleansed. Looking at the uterus, he determined that it contained a fibroma, and impressed by the amount of mess that was about, he resolved at once to remove it. As his method of doing this is fully detailed in his writings, I shall not enter into a discussion of the process, suffice it to say that the neatness and dexterity he displayed forced the conviction on me that I was witnessing the performance of a real professor of the surgical art, and thrilled me with a sensation which a lover of music who had never heard other than second or third rate performances would feel were he suddenly to hear the strains of a Paganini. But to complete the history of the case under consideration. It was found that an adhesion which had existed between the rectum and the tumour on the left side, was persistently oozing. To view it properly, he used a reflector, which he held by its handle between his teeth. There was no room for a ligature, and Mr. Tait first tried pressure with a sponge. As this failed to stop the oozing he rubbed the surface over with a piece of solid perchloride of iron, and as even this did not completely succeed, he made a watery solution of the perchloride and applied it with a sponge. He then dried out the abdomen with sponges, inserted a drainage tube, and stitched up the wound. The whole operation took 50 minutes, an unusually long time for Mr. Tait to take over any operation.

Here I would say a word as to a use of the drainage tube, which is but imperfectly understood, and that is its good effect in stopping bleeding from torn adhesions. Blood effused into the abdominal cavity shows little tendency to coagulate save in a very fitful and fragmentary way, probably from its admixture with peritoneal fluid. If, therefore, there is oozing from torn adhesions into a completely closed abdomen, the blood does not coagulate fully, its presence sets up free secretion of peritoneal fluid, which reacts and leads to further bleeding, and still more defective coagulation; whilst on the other hand, if a drainage tube is employed,

and the pelvic cavity kept dry by frequent withdrawal of blood and serum, oozing will soon cease.

The operation in question having been completed, we—that is the pupils and myself—silently left the room, and soon left the house. Next morning I got a post-card, saying that there would be two operations at the Private Hospital at 9.30 a.m., and one at the Women's Hospital, Sparkhill, at 2.30 p.m. The first was a doubtful case of distension of the gall-bladder. In less time than five minutes Mr. Tait had opened the abdomen over the region of the gall-bladder, established the diagnosis of malignant disease of the transverse colon or omentum, and closed the wound. I learned afterwards that the patient left the hospital in a week none the worse. Of course had the case turned out to be one of gall-stones, she would have been relieved of her trouble there and then. In the afternoon I saw an ordinary case of removal of the uterine appendages. I shall not stop to discuss this class of cases; the one that I saw on this occasion was certainly an instance where the operation was perfectly justifiable, judging from the condition of the parts removed. When the operation began, I took out my watch to time it; having carefully looked at it, I put it in my pocket and turned to the operation table, when to my surprise I saw that the abdomen had been opened and Mr. Tait was fishing with two fingers of the left hand (which was all the incision would admit) for the diseased organs. On getting these between his fingers, he slipped down a pair of forceps, seized them, and in this way brought them to the surface, at the same time pressing down the abdominal incision and walls with the back of his hand, and holding the ovary and tube between his fingers. He then passed the ligature through the pedicle, ran the loop over the appendages, arranged the Staffordshire knot, pulled each end firmly, tied a single knot, and fastened a pair of catch forceps on each of the threads, wound the thread three or four times round the handle of the forceps, and seizing a pair in each hand he let go the ovary and firmly pulled the knot tight. This method of securing the knot he carried out without the slightest assistance, and while he held the parts to be removed in his own hand. I describe it thus in detail in the hope that I may convey to you some idea of the marvellous dexterity of the man. The other side was similarly dealt with, and the operation was completed in ten minutes. Mr. Tait only spoke once during that time. Just when the patient was laid on the table, the sister who was giving the anæsthetic put out her hand to lift the patient's arm on the table. Tait tapped her on the shoulder and said, "Attend to your own business." This is quite characteristic of the man. He has everything reduced to a perfect system, and everything goes on with just such steady regularity and apparent simplicity as do the manœuvres of a well-drilled regiment of soldiers. Trespassers, however, even be their fault as slight as the one I have just mentioned, are at once rebuked, just as the soldier would be who ventured on any irregularity during parade.

Among the other cases I saw operated on were a simple ovariotomy, which was completed in five minutes, neither sponge nor fingers having been placed within the abdominal cavity, and the incision being not more than one and three quarter inches long; a difficult ovariotomy; removal of the tubes containing pus; removal of one ovary and tube glued together, and adherent to the back of the uterus and floor of the pelvis, the other ovary having been removed five years previously. In passing I may remark that Mr. Tait has ceased to remove single ovaries (except for cystic disease), as his experience is, that for inflammatory mischief a second operation always becomes necessary sooner or later. I was also present at a hysterectomy, and at an exploration of the kidney. In this latter I saw illustrated the value of pressure in checking hæmorrhage. The wound was of course a very deep one, the pelvis of the kidney being opened into, and the bleeding was very free, much freer than mere oozing; but to reach the bleeding points would have involved enlarging the incision very much. The wound was packed full with dry sponges, and these were firmly held down by the hand for two or three minutes. On taking them out the bleeding was markedly diminished, but had not ceased, so the packing was repeated, and again repeated, when it was found that the wound remained dry. A drainage tube was inserted, and the stitches were tied with a running loop-knot, with long ends so that they might be undone if required. Instructions were left that, should hæmorrhage occur, a solution of perchloride of iron was first to be injected through the drainage tube, and that should this not succeed in checking it, the knots in the stitches were to be slipped, the clots cleaned out, and sponges wrung out of perchloride of iron inserted and firmly packed in. The sponges that were used were simply wrung out of plain water. I have since learned that all the patients I saw operated upon made prompt and good recoveries.

One thing I saw Mr. Tait do which I certainly have no intention of imitating him in. He used two of the fingers of his left hand as a sort of Sims' speculum, and, kneeling by the bed-side with the window facing him—the field of operation therefore completely in the dark—he freely curetted the uterus, without in any way fixing it. He then inserted a short Ferguson's speculum, and through this passed into the uterus a thermo-cautery. No doubt the cervix had been previously fully dilated, and probably the end in view was satisfactorily accomplished, but I hardly think the somewhat free and easy method I have described will commend itself to the profession at large. Though Tait may manage to dispense with the ordinary aids of speculum, light, and vulsella, the general run of us I think had better continue to perform our curettings in a more orthodox fashion.

I was disappointed in not being able to see Mr. Tait perform the operation which bears his name for restoration of the sphincter ani and perinæum, as the written descriptions of it are not very easy to follow. I talked it over with his assistants, and they told me that he only takes five or ten minutes to do it.

It may have struck you that I have alluded to two operations which went no further than exploration—one of the liver and one of the kidney—and here I would say a word in regard to Mr. Tait's position on the subject of exploratory or confirmatory operations, for, in respect to this more than to almost any other question, he has been very greatly misrepresented, and I shall, as far as possible, make use of his own words. We have all heard him spoken of as a man who "would put his hand into a women's abdomen with as little compunction or reflection as he would put it into his trouser pocket," and also we have heard him quoted as saying when in doubt as to diagnosis, "Open the abdomen and find out," or even more grotesquely, he has been accused of not being able to make a diagnosis in the ordinary fashion, but of opening the abdomen and taking a look in when

there is a complaint of anything inside, and of doing this in as much a routine way as one opens the mouth and looks in when there is a complaint regarding the throat. Let me quote his own words:—"I have long since thrown the uncertainty of diagnosis as an impediment to the adoption of proper treatment to the winds, and when I find my patient in danger of death from conditions within the abdomen which do not seem to be clearly of a malignant character, but a correct diagnosis of which is impossible, I open the abdomen and at once make the diagnosis certain, and successful treatment possible." This was written in 1876, and at a later date, he says that he does "the same thing when the conditions were such that the patient's life was a misery by reason of suffering which could not be relieved, or at least had not been in any other manner. The result has been an enormous advance in abdominal surgery, obtained only after a severe struggle with the authority of the elders, who asserted that the abdomen was a region into which the writs of ordinary surgical laws should not run."

As a defence of exploration, I would further quote from Mr. Tait's writings:—"This principle of exploration is nothing new; in fact the way it is sometimes used or rather abused is almost terrible. I once saw a surgeon who is now a baronet remove a breast with a tumour in it, and after the whole thing was over he took the tumour in his hands and drew his knife across it, and out rushed a lot of pus—'laudable pus.' He had made his exploration after the treatment had been completed. If he had explored first, his diagnosis would have been completed before his blunder had been made, and the surgical operation and treatment rendered unnecessary. I have similarly seen a limb amputated for a sequestrum opening into the knee-joint, which a preliminary exploration would have shown to have been capable of removal without amputation, and the limb would have been saved. Crowds of illustration of this kind of practice could be given, showing in the first place that complete accuracy of diagnosis is no more possible in the breast than it is in the abdomen, that exploration is a sound principle when there is doubt, and that many ghastly blunders would be saved if the practice were extended into general surgery. Absolute accuracy of diagnosis in the abdomen is very far from being possible; only the ignorant assert that it is, and only fools wait for it." More than any man, or I might almost say single handed, Mr. Tait has established this principle of exploration in doubtful cases of abdominal disease when life is threatened. He has been the better able to do so from his extraordinary success as an operator. But what one man has done another may do, and I can quite well foresee that before long it will be considered as bad practice to allow such cases to die without operative interference, as it would now be to leave a man blind from cataract, without giving him the chance of again enjoying the blessings of sight, for fear that an inflammatory attack might necessitate removal of the whole eye.

Another charge that is frequently made against Lawson Tait is that he does not tell the truth. The statements he had to make regarding his work in the earlier years of his practice, were so startling and novel, that they were not at first accepted as true. Time—the righter of all wrongs—has proved by results that the facts and theories then advanced can and have stood the test of experience, and though Mr. Tait's theories and deductions are now very generally accepted as correct, the impression caused by their startling enunciation still finds expression in the charge of untruthfulness I have just mentioned. Now, it is absolutely impossible for Mr. Tait to tell lies regarding his operations or his results. Of the four pupils who watch every operation, each keeps an accurate note-book for his own reference and use, in which he details everything that happens, both in Mr. Tait's hospital and private work. This has gone on for years; Mr. Tait's results are published down to February 2nd of this year; yet they have never been questioned by any one of those who, had there been occasion and justification could have done so successfully. May I say more—that I have met eight or ten of Mr. Tait's past pupils, and not one of them doubt a word he ever said. They have seen what others have not seen. They have had personal opportunities of detecting any such tendency to perversion of the truth, but one and all they have expressed their unbounded admiration for the man and for the surgeon. I had myself good opportunities of forming an estimate of the character of the man. We spent together from Saturday to Monday at Malvern, as guests of an old Scotch practitioner there, and many were the topics that we discussed. I do not wish to make this anything of the style of the modern society journal, so I shall not enter into the private life of the man, I shall only say that I found, as I was fully prepared to find from a perusal of his writings, that he is a man of master intellect, that the range of his knowledge is wide and far reaching, that the accuracy of his knowledge of details is surprising, that his tastes are refined and cultivated to an extraordinary degree, and that his capacity for the enjoyment of recreation, amusement, and the good things of the world generally is unlimited. As to the type of his mind, I would say that it is essentially mathematical and scientific, and I would ask you, is it not your experience that those possessed of minds of such a type are naturally and instinctively, as well as habitually and by training, rigid sticklers for the truth?

Before concluding, I would briefly touch upon three outstanding departments of Mr. Tait's life-work. Already I have referred to what he has done in establishing the principle of exploration as applied to the abdomen. One outcome of his work in this direction has been his demonstration of the fact that very many of the cases where masses are felt at the sides of the uterus, and which are called peri- or parametritis, and are treated as such, are really cases of occlusion and distension of the Fallopian tubes with fluid of various kinds, or of chronic inflammatory adhesion of tube, broad ligament and ovary; cases in which the functional utility of the organs is completely destroyed by disease, and in which, further, the disease in some cases—such as pyosalpinx—constantly threatens the life of the patient; while on the other hand he has demonstrated that such cases are quite amenable to surgical treatment. What suffering he has relieved and averted, what life he has saved and prolonged by these means passes my ability to conceive. His work too in elucidating the natural history of uterine myomata, and in elaborating their surgical treatment, is to my mind of the greatest interest and importance. His papers on these subjects, at present appearing in the *Birmingham Medical Review*, will well repay careful perusal, and ought to prove an effectual antidote to the effects of the electrical mania which is at present rampant. And finally there is what I consider the crowning triumph of his life, the establishment of the principle of immediate abdominal section in cases of ruptured tubal pregnancy by his magnificent results—two deaths in forty-two cases—of an accident which, without interference, is uniformly fatal.

CHILL, OR RIGOR.

By William H. Pearse, M.D. Edin.,
Senior Physician Plymouth Public Dispensary.

(*Continued from page* 406.)

4. *Gradation of Fevers, Inflammations, etc.*—Under the last heading of "Approximative Groups of Diseases which have Rigor as a Fundamental Stage," I have cited some border-land types of fever and inflammations in order to see that Rigor holds the same place in them as it does in typical fevers and inflammations. I propose now to further view some of the gradations of fevers, inflammations, etc., and thus yet more to see the fundamental unity of method and the wide common Forms or order of nature in disease. I shall only briefly cite some instances, mainly drawn from the observation of disease, in Cape voyages from England to Australia, and from Calcutta to the West Indies; in all cases with many hundreds of people.

Scarlet fever with eruption, sometimes with and sometimes without sore throat, existed during the first nine weeks of the voyage of the ship *Tarquin*, Plymouth to Adelaide, 1864. There was also a series of sore throat cases, of most varied degrees of severity, accruing during the same period. The sore throat cases continued to appear during weeks after the scarlet fever cases had ceased; but there evolved also, and mostly in later weeks of the voyage, bronchial febrile cases, which commenced as sore throat; diarrhœa febrile cases, which commenced as sore throat. Also there evolved febrile attacks after shivering, which were called by the patients, "aching bones"—"Can't keep heat in me." These ended in bronchial affection. When in presence of the phenomena I was deeply impressed with the continuity of the whole series.

In the ship *Adamant*, Plymouth to Adelaide, 1864, there was a series, in continuity, of scarlet fever, redness and ulcers of the tonsils, simple redness of the tonsils, febrile diarrhœa, and "colds," or febricula. It was impossible to say whether certain cases were scarlet fever or sore throat, or diphtheria. I have seen paralysis follow what could only be regarded as cynanche tonsillaris. In another case long continued paralysis followed what could only be regarded as scarlet fever.[1] The cases of sore throat were obviously as "general" diseases as were the scarlet fever cases. The sore throat cases presented the most varied types. In different voyages in high south latitudes I have seen epidemics of cynanche tonsillaris; some of the cases were of extreme severity. Young women would have a rigor in the night, and the next day the tonsils would be each a mass of white slough. Whooping-cough and scarlet fever co-existed in one case; measles and whooping-cough co-existed in another case.

In the ship *Hougoument*, Plymouth to Adelaide, 1867, a case of scarlet fever showed in the sixth week, and another in the eleventh week. There had been a continuous epidemic of measles during the first eleven weeks of the voyage—twenty-eight cases in all; but there was a continuous series of sore throat cases from the second to the fourteenth week. In striking continuity with both the measles and sore throat cases were a continuous series of "colds" (febricula) and diarrhœa. The first and only case of whooping-cough evolved in the tenth week, in 41° S. L., 6° E. L.

I was at the time deeply impressed with the seeming alliance and continuity of the measles, "colds," and diarrhœa; the "colds" and diarrhœa were general febrile cases; the Form or symptom most common to them all was rigor.

Measles, in different voyages, showed the most striking variation; in one epidemic the longest duration of the disease from first ailing to the return to normal temperature was ten days; the least duration of other cases in the same epidemic was three days. The highest temperature in any case was 103°; the highest in some other cases was 99°. Whatever be the profounder nature or Form of the pathology of measles, I was often forced to conclude that the lung affection was of greater place than other symptoms—that is to say, that although we properly enough confine the word measles to a febrile disease having a special eruption, and of an infective and epidemic character, yet bronchitis is so early and constant a symptom, that we are led to look, in the deeper pathology of measles, for some blood or protoplasmic type of change, which is common both to measles and to acute bronchitis. In many voyages I have observed a prevalence of a type of cases commencing with rigor, and followed by headache and diarrhœa. They usually happened in high south and cold and depressing latitudes; they were of a fever type. In other voyages downright continued and fatal fever evolved, in the same latitudes and environment.

But it was often very strikingly seen, with natives of India, that in colder "Cape" latitudes they would suffer intermittent fever, in some of its irregular forms (ţap), and which would be followed by, or almost immediately associated with, bronchitis or diarrhœa. It would be to take a very limited view of such cases to consider them as simply bronchitis or diarrhœa; they were cases of fever—general diseases—of which the bronchitis or diarrhœa were after-stages. The protoplasm of the native of India, owing to long ages of sameness and deficient food, and to the exhausting influences and trying extremes of the climates, may be viewed as in a state of unstable equilibrium. The slightest change of place, wind, and sometimes even the mere eating a meal, will induce fever of an irregular intermittent type, which very often will pass on to bronchial affection or diarrhœa. Indeed, in too many cases I have seen the native sink and die, with slight diarrhœa or bronchial affection, which commenced with slight fever. Natives of India will often die where, as far as local affections go, there has been no cause for death; and yet one could almost with certainty predict their death. Such cases, like to those of diarrhœa and bronchitis, with slight febrile onset, point to primary devolutions of protoplasm which are not yet recognizable by structure or by our present powers of chemical analysis, and which change the correlations of mode on which the complex and delicately-equipoised harmonies of life depend. Natives will be seemingly well; a slight intermitting fever (tap) will occur in the evening, followed by two or three motions in the night; there will follow a collapse, out of all proportion to the amount of diarrhœa. Such cases will often get weaker and weaker, and die. To say that they have died of diarrhœa is no just measure of such cases. The whole protoplasm, like to that of a leaf in Autumn, seems to be of an expended vital energy. Such individuals are ever near to those degrees of protoplasmic devolution, which result in cholera. No specific difference separates the

[1] See *Medical Press and Circular*, January 7th, 1880, p. 3.
Surgeon J. Hume, of Amrasti, India, reports a case of paralysis of the upper limbs after small-pox.—*Indian Medical Gazette*, December, 1883, p. 351.

"tap" of the native, with its slight yet fatal diarrhœa, from the graduations of cholera. In these obscure and ill-defined fatal diseases of natives rigor is the primary deviation.

I cite the following cases to show the variation of disease with changed environment. This special variation was seen in the cardiac system. Low pulse followed in the series which rigor initiated. One cannot avoid asking the question: Was the rigor the primary stage of the evolution of poisons in protoplasm and the blood, whose action on cardiac centres was like to that of known vegetable cardiac depressants? Did a reversion of protoplasm happen toward bodies isomeric, or of like molecular energy and power, to some of the known vegetable poisons? The cases occurred in the ship *Hougoument*, Plymouth to Adelaide, 1866. An epidemic of measles existed.

On June 26th, in 19° N.L., 21° W.L., Reed, m., æt. twenty-five, showed measles. "Yesterday evening shivered; was hot in the night; had pains in legs and arms; pulse 100; copious eruption of measles; tongue large and moist, slightly coated.—June 27th: pulse 75; copious eruption; skin cool.—June 28th: cool; no pains; eruption out full; pulse 72.—June 29th: copious eruption; cool.—June 30th: pulse 44; says he is well."

On the same day as that on which Reed showed measles—June 26th—Cunningham, m., æt. twenty, said: "Was well yesterday evening; felt a slight shivering at bed-time; was restless during the night; took a sea-water bath at 2 a.m. this morning; had several motions; pulse 60; cool; dull-looking.—June 27th: pulse 48; cool; no pain.—June 28th: pulse 48, regular; seems well."

On the same day—June 26th—Pattison, m., æt. thirty. "Shivered yesterday, . . . weak, dull, . . . tongue full, soft-looking, whitish, . . . a patch of dirty yellowish ulceration on back of pharynx; . . . a little redness of fauces; . . . uvula slightly swollen; . . . says he is very weak; looks dull and depressed; pulse 56."

In the same latitude, Glachlan, m., æt. twenty-one, showed measles on June 27th; pulse 140.—July 4th: 8° N.L., 25° W.L.; pulse 66.

In the ship *Tarquin*, when about on the Equator, on September 20th, 1864, the following case showed: Coleman, m., æt. twenty. "Has had offensive breath for ten days; now worse; says he is very weak—no spirit; no cough or shortness of breath; no dulness on percussion on chest, save perhaps on a spot in left (infra?) axillary region; some few moist râles heard there; breath-sounds heard good everywhere; no pain in liver; liver natural size; at times some pains across abdomen; bowels open; vomits sometimes; voracious feeling of appetite, but yet cannot eat; gums a little scorbutic; pulse 20."

I have seen slight bronchial attacks, a few weeks after sailing, show quite a collapse and low pulse.

I have cited these varied types of disease—scarlet fever, measles, "colds," irregular intermittent fevers, bronchial fevers, diarrhœa, slow pulse cases, etc., as illustrations of the great truth, that even to common observation, the phenomena we group as distinct and specific diseases, are not fixed. With the change of environment, which is involved in a voyage from 50° N.L. to high S.L., the protoplasmic pendulum oscillates wider than under its habituated environment of evolution and physical correlations; or in chemical language, the reactions of protoplasm under the new and varied reagents and physical existences of different climates, take a wider range, and producing new bodies, or new molecular conditions in protoplasm, cause the low pulse. The pulse of cases of measles was like to the pulse of cholera. It seems like an *à priori* truth, that a *common type* of the devolution of protoplasmic albuminoids must have occurred in all the so-varied diseases; and again I must remark that rigor was the so-far primary fact in all.

5. *Gradations of Fevers, Inflammations, etc., further illustrated*.—W. H——, æt. thirty-five, m., a cabman, was well on the morning of April 23rd, 1889. He went to his stable, and there had a rigor. I first saw him on April 27th. From the 23rd to the 27th he had had pretty constant vomiting of greenish bile; also much purging. On April 27th (temperature 101°, pulse 100) I found pneumonia of right apex; the small lobe of liver was a little painful on percussion; no abdominal tenderness; no albuminuria; he was bright and cheerful, but had wandered in mind a little during two nights. He was flushed and anxious-looking. He had drank freely for six or eight months past. I prescribed ℥i. of tinct. aconit. with gr. xv. pot. bromid. every two hours; cold water as a drink. April 28th.—Pulse 100, temperature 100°. The pneumonia at right apex was very slight in extent; dulness on percussion less, and crepitation less. The patient now passed from my care to that of Mr. L. Pilkington Jackson, who prescribed effervescent salines. Mr. Jackson informs me that the temperature remained at 100°, the pulse constant at 108. Day after day he became drowsy; the vomiting and diarrhœa continued up to forty-eight hours of his death, when both ceased. No new localisations developed. The drowsiness deepened, and he died on May 6th, fourteen days from the primary rigor. From my first visit, I thought that the man would die, though the localisations were but slight; but how did death result? I can form but one hypothesis—that the primary rigor indicated disturbance of protoplasmic correlations; or in chemical language, that new bodies evolved out of the protoplasm, which acted as veritable poisons. The extreme vomiting, from the date of primary rigor, and lasting twelve days, showed that poisons had evolved in the protoplasm, just as surely as if he had taken apomorphia or tartar-emetic. Such a case I should treat by Warburg's tincture, or by the hypodermic injection of quinine.

A pensioner, of fine physique and of good general health, had a rigor one night after exposure on a pier. He developed some congestion at the base of the right lung. There was no marked dulness on percussion, no true crepitation; but he had dusky countenance, numerous petechiæ, dark dry tongue, much delirium, and great jactitation of forearms and hands. He had the aspect of typhus. There were no localisations of importance. He died ten days after the primary rigor. Of what disease did he die? I can but form the hypothesis that the amazingly complex and highly-differentiated protoplasm—blood, cell-contents, etc.—reverted in the rigor to less vital vito-chemical bodies, which were inharmonic to his survived and then-present modes of vital being; in chemical language, that poisons evolved in his system. He had not the extreme vomiting of W. H., but the stupor was greater. One cannot but ask: Did bodies isomeric with or of like mode or molecular motion to some of the opium, diethyl, or dimethyl-methane, etc., series, evolve in these cases?

E. P——, æt. sixty, a fine, active man, of highly sensitive temperament, remarked on the evening of May 23rd, 1880, that he felt unusually well. He took an evening walk, and had a rigor in the night. I found him at 10 a.m. the following morning with the aspect of a man death-stricken.

The heart's action was tumultuous, without endo- or pericarditis. A slight pleurisy developed at the right base. He died on May 29th, of suffocative bronchial râles, which had daily accrued. His aspect the morning after the rigor showed death; pulseless at the wrist, the heart tumultuous, the countenance pale, in cold sweat, and anxious. He had a large thorax and large lungs, but mucous day after day accumulated in the tubes. The molecular correlations of his protoplasm were disturbed in that rigor, as surely as are those of the native, when bitten by the cobra in the hot season. Some poison, or inharmonic molecular mode and motion evolved in and of the rigor. We have ceased our surprise at the amazingly different powers which isomerism and allatropy in the inorganic and organic worlds show us. We may be sure that the Form or law of continuity does not abruptly cease at the threshold of the actually living. The symptoms which follow rigor in different cases simulate the effects of a great many of the vegeto-alkaloid poisons. It seems as though albuminoids and protoplasm, in their evolution, held dormant or latent the vast series of the earlier vegetable products. These latter, or bodies isomeric or allied to them, seem to be absolute parts of the reversion or death of albuminoids and protoplasm. E. P——'s aspect the morning after the rigor was like to that produced by the administration of a fatal dose of nicotine.

A girl, æt. fourteen, previously healthy, "took cold" at a Sunday School treat in the country. She had a rigor on the evening of her return home. Until her death, five weeks after, I could never venture to give the disease a name. It was a case of continued fever. Sometimes the symptoms inclined one to class it as typhoid; at other times, it looked like threatened tubercular meningitis—but I could never say which it was. The *post-mortem* revealed nothing: there was no sign of typhoid in the intestines, and no sign of meningitis within the cranium.

J. C——, m., æt. fifty, consulted me on November 7th, 1879. He had chronic abscess of the sub-maxillary glands. He said that he had similar abscesses when a young man. He had led an active and intellectual life. I prescribed pot. iodid. and tinct. bark; also cod-liver oil; and advised his going away for change of air. He did not, however, go away. On November 27th, he attended a public meeting in a large, new, and damp building. Rigor followed on the same evening.

November 28th: 8 p.m., temperature 102.8°; pulse 120; breathing 20; slight fœcal smell of breath. The bowels, which habitually were regular, had not acted from the 21st to 28th; on the 28th they had moved after the use of some aperient pills.—29th: Temperature 101.2°.—30th: Temperature 100°; pulse 100; no vomiting.—December 1st: Temperature 98.6°; pulse 90; no pain; no vomiting; two natural motions.—2nd: Temperature 100.4°; pulse 88; no pain; not sick; four motions; no wandering of mind.—3rd: Febrile smell of breath; no pain; no aching of limbs; no wandering of mind; feels prostration; no motions; pulse regular, but weak.—4th: Temperature 99.3°; pulse 90.—6th: Temperature 98.2°; pulse 86; sleeps much; no head symptoms; one motion; no spots on skin; no pain; tongue dry.—7th: Temperature 97.4°; pulse 90; tongue dry; says he is better.—8th: Temperature 100.4°; pulse 96; bowels confined for three days.—9th: Temp. 99.4°; bowels open once with full pultaceous motion; no blood; no pain; tongue dry; no wandering.—10th: Temperature 97.6°; pulse 120; vomited green bile; feels sick; tongue moist; no tremor of wrists or limbs; pulse feeble.—11th: Temperature 96.5°; pulse 100.—11th, evening: Temperature 98°; bilious vomiting; two liquid motions.—12th: Liquid motions; vomiting; no pain.—13th: Temperature 97.4°; pulse 90.—15th: Vomited bile; natural motions.—17th: No vomiting for two days past.—18th: vomiting returned; one motion; fell off the commode in syncope, and died in an hour of hydrops bronchialis.

In the earlier days the liver was large, but returned to its natural size. The pulse was small for a few days before death, and I now and then in the later days found a semi-intermission. No complications or localisations of disease could be found. The patient was a bright intellectual man, and always received me with brightness and cheerfulness. I assumed that I had a fatty heart to deal with, and urged the use of the bed-pan; he would not consent, and fell off the commode, and died. The basis of treatment was quinine, dissolved in a mineral acid. Opium was now and then used to check diarrhœa. Alcohol was freely given. But what name, having any scientific precision, can I give to the case? Suspended or lessened conditions of the vital energy were seen in the existence of chronic abscess, and in the suspended action of the primæ viæ—the seven days' constipation. The patient had no localisations of any kind, except some fulness of the liver during the first week. No sign of abscess of liver could be traced; no albuminuria; the vomiting was not associated with inflammation of serous membranes, or of the diaphragm.

Had the system absorbed poisons from the alimentary canal during the seven days' costiveness? On November 28th, though the bowels had on that day moved after the use of pills, the breath had a fœcal smell; but a deficient vital energy must have existed which led to the costiveness. Costiveness is not an affair confined to the bowels. The whole system must have been in low energy, and of which the costiveness was but one sign. Then followed the rigor on November 28th, followed by slight pyrexia for six days. After this came a prevailing sub-normal temperature for two weeks, and death from the heart.

Mr. W——, æt. thirty-five, I saw on October 15th, 1884. He had had violent delirium and much excitement during the two preceding days and nights. Temperature 98°; pulse 84, regular. There was some congestion at the base of the left lung. Seven days ago he had rigor. The delirium was sympathetic (so-called). Shall we ascribe the delirium to the acute congestion of the base of one lung? or shall we not rather view the lung affection and the delirium as having a base in common, in some changed conditions of protoplasm, induced with and of the rigor?

Professor Caley tells us "that theoretically, for a body whose formula is C_{13} H_{28}, there exist 799 isomeric bodies. It is worthy of remark that the mathematical theory agrees with experiments for the first five bodies, thus affording strong confirmation of the truth of the remainder" ("Nature," vol. xii., p. 483, Report of B.A., Bristol, 1875). With such a range of isomers, from so simple a combination as C_{13} H_{28}, may we not justly expect that a vast range of isomeric bodies shall evolve or revert out of the complex and highly-atomic albuminoids? Do we not know further how intensely unstable are some groups of the N compounds, and how vast is the molecular energy of bodies of the N series?

To what direction *must* reversion of protoplasmic albuminoids tend, but to the earlier-typed vegetable organic bodies? Evolution and devolution, or reversion, must be

in absolute continuity. "In the midst of life we are in death." If we hold the doctrine of cosmic evolution, there *must* be a continuity and correlation between all animal products and the productions of the vegetable world. That opium will deepen sleep proves the absolute continuity of the molecular Forms of opium and nerve protoplasm. Sleep is not a thing or entity added to the body; it is an evolution in an exact and orderly method in and of the modes or molecular motions of protoplasm. In the cosmic evolution opium must have a harmonic molecular fitness to the modes of nerve cells; and so in reference to all other poisons and drugs—*e.g.*, nicotine, strychnine, etc. We see parts of an as-yet-unread law of molecular energy and motion, whose results are the organic, and life, and health, and disease. Are we justified in holding that in the cosmic evolution, the vegetable higher differentiations, the carbo-hydrates, the fatty acids, the aromatics, the alkaloids, are earlier and more simple than are the higher albuminoids? Is it not a just *à priori* expectation that protoplasm, in its reversions, should pass into a vast series of bodies, isomeric with the vegetable alkaloids, aromatics, fatty acids, and carbo-hydrates? And do not the symptoms of the so-called different diseases seem resultants of such reversions? And does it not seem that rigor is here involved, as the most fundamental, yet recognised, Form in pathology?

There is obviously a great as yet unread law of the organic evolution; the cell must have cosmic foundations and correlations; the reversions of protoplasm must be as orderly, and by law, as is the evolution; both the evolution and reversion must be in continuity, must be parts of one series. The laws of continuity and cosmic evolution compel us to hold that molecular modes, motions, bonds, and properties which are existent in the vegetable kingdom—opium, strychnine, atropine, etc., etc.—must be, in some degree, latent in the higher vital differentiations—*i.e.*, in animal protoplasm: the reversions and devolutions which lead to disease, of necessity *in some degree* take a backward path parallel to the primary evolution; how else can we bring under any law such facts that tetanus, following simple wounds, is indistinguishable from tetanus following the use of strychnine. In the former instance, modes of motion must have evolved in protoplasm, like to those which exist in strychnine. The same reasoning will apply to cases of coma, at the end of various diseases, and the powers of opium. We already know how vast is the variety of bodies obtainable from re-actions, in our laboratories, on albuminoids. They must be infinitely greater in the cosmic correlations of a living cell.

The study of the reversions of protoplasm, as producing symptoms like to those produced by vegetable productions, appears to me to open a grand law in pathology; and not only so, but also to harmonize that law with the method of our therapeutics. That quinine, etc., reduce the temperature, are parts of as simple and universal laws as are those of Kepler in celestial mechanics. These laws must be based on the ultimate energy and molecular motion. The cataclysm within protoplasm, which we call rigor, reveals in its varied yet allied products the orderly reversions, and allows the vito-chemical evolution of a vast variety of poisons out of the protoplasm, which are parallel, if not isomeric, to the higher productions of the vegetable kingdom. These new bodies disturb the molecular harmonies and exquisite equipoise of correlation, on which life at any time depends: here seems an approximative basis in pathology. What I have already said will illustrate the fact that rigor, and the subsequent pyrexia are in point of frequency of occurrence, breadth of their range, and variety in their results, the widest and most general phenomena we have as yet recognized in pathology.

6. *Chill or Rigor viewed Biologically and Chemically.*—I assume that we have reached that state of method by which the doctrines of cosmic evolution and continuity are seen as *à priori* truths. The evolution of cells in all their variety and exalted functions and energies, are as obedient to law, as determinate, as are the mechanical motions, or as are the physical energies—*e.g.*, the wondrous perfection of the sense organ for sight, is an absolute evolution, with and of, cosmic environment and that mode of energy, we call light. The so-far elements of protoplasm C H O N, etc., plus cosmic environment have differentiated into protoplasm; and in an absolute continuity, the protoplasm has differentiated into the highest sense organs. We shall thus recognize that a nerve energy or irritability must exist in the ultimate molecules of protoplasm; but the seeming ultimate molecules are not absolutely ultimate; they obey laws as much as do bodies in inorganic chemical action, and are but necessitous expressions of a yet more remote and pan-diffused energy.

Is it not *à priori* true that every action of life is in absolute continuity with all other chemical laws and Forms, and with the correlatable modes of energy? Is not the cell a microcosm? Dr. Edmund Montgomery says ("The Elementary Functions and the Primitive Organisation of Protoplasm," "St. Thomas's Hospital Reports," vol. ix., p. 96, new series): "Everywhere in the ectoderm the functionating substance is homogeneous, structureless; but, in spite of its ocular uniformity, the chemical differences of its various developmental stages is accurately proportionate to its functional difference at such stages. In fact, the chemical and the functional difference are two aspects of the same reality. The difference in the vital chemistry expresses itself as functual difference." Dr. E. Montgomery further says (*op. cit.*, p. 81): "The very complex organic molecule of protoplasm, at the height of its combination with complemental material is disintegrated by the dynamical powers of the environment." "This single, and very obvious occurrence, so rounded off in itself, and yet so variously related, constitutes the elementary wave of living existence, the primitive pulse of objective vitality." If we hold that life is the result of, and inseparably one series with, the infinite activities and cosmic correlations present in every molecule of protoplasm, it follows that we must seek the basis of disease in no less wide a field, always remembering that disease is in orderly continuity with health.

I have assumed that rigor involves changes in the vito-chemical processes of protoplasm—changes which are orderly and in continuity with normal rates, and in continuity with the fundamental energies of evolution—and which disturb the primitive irritability and capacity for sensation of protoplasm; or, in other words, disturb the harmonious chemical correlations of molecular motion. In the sketch I have made, we have seen not only the great area over which rigor extends, and its great frequency, but also we have seen how great is the number of so-called different diseases which are based on rigor. We seem to be nearing a basis in pathology, coincident with the great Forms of energy, molecular law and continuity. Rigor seems like a revealer of these laws; and not only so, but the method of our therapeutics is seen to be parallel in nature with the method of the evolution

of the protoplasmic albuminoid poisons. One can hardly doubt that alcohol has arrested the catabolism of protoplasm into poisons, after rigor and varied shocks had initiated the vito-chemical devolution. Nor can one doubt that the opium, black pepper, and assafœtida pill of Indian bazaars, has often arrested the full vito-chemical changes, which result in cholera, and which chill had set a-going.

In the study of rigor we can approach by three ways: the physiological, the pathological, and the therapeutical; but these three ways are ever in contact, and are in wider method, one. Until the chemist reveals the absolute laws or order of the evolution of the organic elements, of cells, of protoplasm; and, yet further, until the chemist reveals the laws and order of the reversion of albuminoids, it is allowable that we study by the observation of nature, and by analogy.

NOTES ON A CASE OF ABSCESS OF LIVER.

By F. F. Bond, M.D., Rastrick, Yorks.

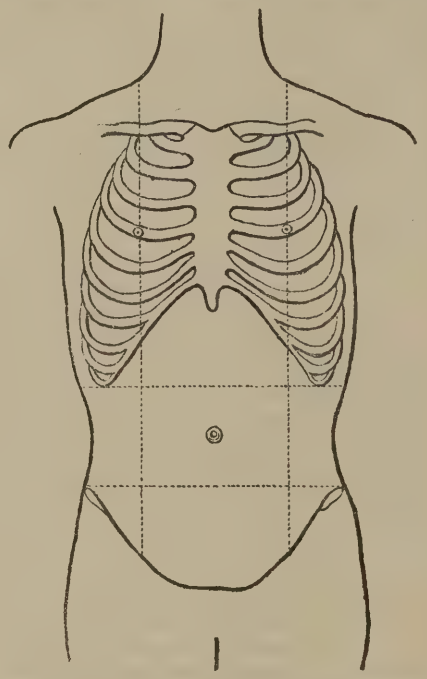
Ernest A——, æt. seven years, came under my care on June 13th, 1888, suffering from acute pain in lower part of chest on the right side, both anteriorly and posteriorly, dry cough, some slight rise in temperature. Physical signs were—increased dulness over lower four ribs; diminished resonance and fremitis, and dry friction murmur heard over same area.

Family History.—The lad, who had previously very good health, was born at Lucknow, the father being a soldier. Father is a strong vigorous man; has had ague. Mother has had repeated attacks of ague; they are otherwise quite healthy; no signs of syphilis.

The patient improved for a few days, then serious dyspeptic symptoms appeared, very frequent vomiting; these were very intractable, and improvement went on very slowly. He was ordered change, and was taken to Scotland on July 7th; here he was much better for four days; then he was attacked with severe pain in the same region as before, accompanied by a swelling just below the ribs in front. The doctor told the parents he was afraid of abscess of liver; the symptoms rapidly disappeared under treatment by blisters, and administration of pot. iod. and hydrarg. perchlor. The swelling had entirely disappeared by August 7th, when he was brought home.

On August 12th he again began to be worse. He presented the same physical signs as when I first saw him, with the addition of an egophony, the friction being only heard at upper part of dull area. The margin of the liver was felt just below the edge of the ribs in front; it was not particularly hard nor tender; appetite poor; bowels costive; stools offensive; no jaundice; urine heavily charged with urates and uric acid, but not albuminous. In addition he had for a few days ague-like attacks every evening, the morning temperature being normal. He was able to get up, and go about in the day-time. A doubtful diagnosis of pleurisy with effusion, causing secondary liver changes, was made. The parents being adverse to any puncture being made, I advised them to take the lad to a consultant, which they did on August 27th. His diagnosis was empyema (no exploration was made); local application of ung. iodi was recommended. After four days the attacks of fever ceased, and he was considerably better, physical signs also almost disappearing. The attacks of fever continued to come on about every nine or ten days, and would recur every day for a few days. The evening temperature would be 103—5; morning normal or subnormal. During these few days he would be very much worse; no appetite; stools pasty, dirty, and offensive; cough very dry and distressing; vomiting very troublesome; also the physical signs became intensified.

On September 17th, during one of these relapses, another blister was applied. The following day he was much better, and in a few days physical signs again almost disappearing. On Sept. 23rd he had another relapse for a few days, but it was not so severe as the present one; the blister was kept open. Oct. 3rd there was another relapse; this time the lower margin of liver became very hard; at one part there was a hard nodular swelling just above the margin in the right hypochondrium, the liver at this point extending over two inches below the ribs. There was



again increased dulness behind. The patient was now very weak and emaciated; bowels acting freely; stools very offensive, thin. The following day another blister was applied over the swelling. Again there was marked improvement, with almost total disappearance of physical signs.

On Oct. 18th he had another relapse, much the same as before. On Oct. 22nd Dr. Dolan was asked to see the case in consultation. The diagnosis was now clearly abscess of the liver; prognosis very grave. It was decided to try another blister, and if that did not relieve, to try aspiration. There was no improvement; the rounded swelling rapidly softened, by the end of the month fluctuation was very distinct, and the prominent swelling evidently adherent to abdominal wall.

On November 1st an aspiration was made, and about two ounces of thick yellow pus drawn off, not bile stained nor offensive. The day following, the side was strapped to give rather more rest. The boy now began to steadily improve. The posterior dulness gradually went down, and disappeared. On November 11th some pus had again collected, and burst through the site of the puncture; it continued to discharge for some time. Improve-

ment now progressed rapidly, cough and pain disappearing; edge of liver softened and receded.

On November 19th very severe abdominal pain came on along the course of the colon; this continued in spite of drugs till the 21st, when it suddenly disappeared. Shortly afterwards he parted with a large quantity of offensive fœces, pus, and blood per rectum. From this time he steadily and rapidly improved, and by Christmas the discharge of pus from the abscess and per rectum had quite ceased. He gained strength and weight rapidly, and was able to go away. I examined him again about the middle of January, when very little trace of the mischief was found. At present he is in very good health indeed.

Regarding the cause, nothing could be ascertained beyond the residence for a time in a malarial climate.

This case is interesting from the great difficulty of diagnosis at the beginning, the symptoms being identical with pleurisy; there was practically nothing to point to the liver as being the source of the mischief. It was not until the marked local swelling over the liver appeared that it became evident the liver was at fault. Again, the course of the case was peculiar, there being the periodical relapses, with intervals of apparent recovery, the temperature in the intervals becoming quite normal. It also seems remarkable to get complete recovery after the bursting of an abscess externally, with probably a second one bursting into the colon.

Treatment.—I found cocaine relieved the cough better than anything else. It was necessary to give pepsine all the time, or the food would return. The diet was almost entirely a milk one, milk and lithia water being freely drunk. During the feverish attacks quinine was given (three grains daily); otherwise the treatment was an expectant one.

THREE CASES OF TRANSFUSION.

By A. W. Mayo Robson, F.R.C.S.,

Hon. Surgeon Leeds General Infirmary; Hon. Consulting Surgeon Batley Hospital; and Lecturer on Practical Surgery at the Yorkshire College.

As the operation of transfusion is not very common, and as the methods usually described are somewhat complicated, and, therefore, not available at a moment's notice, the history of three cases in which a simple method answered perfectly, may, together with the mode of procedure, prove of sufficient interest to relate.

Case 1.—I was urgently summoned late one evening, by her medical attendant, to see Mrs. A——, aged thirty, and on arrival found that she had been delivered of a child, at the full term, about an hour previously; and that immediately after the extrusion of the after-birth, such profuse flooding had occurred, that the patient's life had been greatly endangered, for, despite the administration of ergot subcutaneously, the use of the hot uterine douche, and the exercise of continued pressure on the uterus, whenever the hand was taken from the abdomen, the cavity of the womb at once began to be distended with blood. When I saw the patient, she was almost pulseless, and, although the hæmorrhage had been arrested, she was only conscious when roused, relapsing into a dreamy state almost immediately. The foot of the bed had been raised previously. Frequent subcutaneous injections of ether were given, and an enema of beef-tea and brandy was administered. Owing to her critical condition, we thought it advisable to perform transfusion. As the patient seemed not unlikely to die, Mr. Jessop was asked to meet us, and with his concurrence, transfusion was performed as follows. The husband volunteered to give the blood, and whilst I was exposing the vein of the patient, and introducing the pipette of an Aveling's transfuser into the median basilic vein, Mr. Jessop bled the donor to eight ounces; the blood being received into a clean warm basin, in which it was well whipped with a silver fork for a few minutes, and then filtered through fine muslin into a saline solution, made by mixing a small teaspoonful of ordinary table salt with a good tumblerful of warm water. This mixture, after having been again passed through muslin, was injected gradually by means of the Aveling's transfuser, which had been previously filled with saline solution, in order to avoid the possibility of air being forced into the circulation. On the third syringeful being injected, the patient, who had been unconscious, even to not feeling the incision, opened her eyes, and in a dreamy manner said, "Oh! I begin to feel warm all over." About half a minute was allowed to elapse between the injection of each syringeful. After fourteen ounces had been injected, the pipette was withdrawn, and a catgut ligature, which had previously been passed round the vein, by means of an aneurism needle, was tightened and cut short: the wound having been irrigated with an antiseptic solution, the edges were drawn together by two catgut sutures, and a piece of antiseptic gauze was placed over and retained by a bandage. The patient was then perfectly conscious, had a fair colour in her lips, and expressed herself as being quite comfortable. She was quite unaware of any operation having been performed; and, until some days afterwards, when she asked what was the reason of the bandage remaining round her arm, she did not know by what means her life had been saved. Her recovery was uninterrupted, and she is now in perfect health.

Case 2.—About seven o'clock one evening, I received an urgent message from my brother, Mr. Herbert Robson, to go and see a patient of his with him, a Mrs. A——, aged thirty-seven, and to be prepared for transfusion. On arrival, the history given by my brother was, that he had been called to see his patient only an hour previously for what was supposed to be a miscarriage; that she had been flooding the whole of the day, and had only sent when she seemed to have lost an alarming quantity of blood. The uterus had then not emptied itself, and, as the patient was almost unconscious and pulseless, it was feared that any attempt to clear out the contents of the womb might end in fatal syncope. The uterus had been plugged, and a firm binder applied over the abdomen before my arrival; but despite ether injections and raising the bed, the patient showed no signs of rallying. Transfusion was at once proposed to the friends, and the daughter volunteered to give the blood, which was taken from the vena salvatella; four ounces being received into ten ounces of saline solution, made by putting a teaspoonful of ordinary salt into a tumblerful of warm water; this quantity of filtered blood and salt water, was introduced by means of an Aveling's transfuser, and at the end of the operation, which occupied about ten minutes, the pulse had returned, some colour had come into the lips, and the patient had regained consciousness. Recovery was uninterrupted, but slow. Two days afterwards, the patient had so far recovered, that my brother dilated the os, and ventured to empty the uterus of its contents. She is now perfectly well.

Case 3.—Mrs. R——, was admitted to the Leeds General

Infirmary, suffering from cancer of the uterus, which had been bleeding for some weeks, to such an extent as to completely blanch the patient. Colpo-hysterectomy was performed and rather free bleeding occurred, which, however, was arrested before the patient was put to bed. When seen about eleven o'clock at night, there had been some oozing from the vagina, not of blood, but of serous fluid, which, in her ex-sanguine condition, had rendered her pulseless; but the effect was no doubt partly due to shock. The blood being offered by the husband of the patient, transfusion was performed at once, by bleeding the donor to the extent of four ounces into eight ounces of a five per cent. solution of phosphate of soda, the filtered mixture being introduced by means of Aveling's transfuser. After the operation the patient rallied for a time, but subsequently succumbed; the life having been apparently prolonged by the transfusion for a few hours, and consciousness having been regained.

Although it has been known for some years that a solution of phosphate of soda prevents the coagulation of blood, to Dr. Braxton Hicks, "according to Mr. Bryant," belongs the credit of suggesting its use in transfusion. In the *British Medical Journal* for January 30th, 1886, Dr. John Duncan published an interesting paper on Transfusion, recommending one part of a five per cent. phosphate of soda solution to three of blood. In the same journal for April 10th, 1886, Mr. Lawson Tait published a paper advocating transfusion. He employed two ounces of phosphate of soda solution to six ounces of blood, using a glass nozzle with a tube and syringe, and occupying twenty minutes in the operation. Kronecker in the *Deuch. Med. Woch.* for August 7th, 1884, relates experiments on the transfusion of saline solution into dogs, which he bled until they had lost from half to two thirds of their blood, afterwards injecting 6% solution of chloride of sodium in distilled water, in amount equal to the blood withdrawn, recovery ensuing. He says as the result of these experiments, that a seven per cent. chloride of sodium solution is thoroughly efficient, without the use of freshly drawn blood. In the cases that have come under my notice, where a saline solution has been employed alone, without admixture with blood, the relief has been only temporary. I should prefer in all cases where I could obtain freshly drawn blood, to employ it mixed with the saline solution in greater or less quantity. As a chloride of sodium solution will retain the blood in a fluid condition for a considerable length of time, there need be no undue haste in completing the operation, which may be hastened or retarded according to the condition of the patient: being more likely that a patient whose depletion has been gradually going on for a length of time, will require the transfusion to be performed more slowly, than one who has been suddenly brought into a dangerous condition by complete and rapid loss of blood.

In the foregoing cases, no special antiseptic measures were adopted beyond strict cleanliness, excepting that the wound was washed out with an antiseptic solution before introducing the stitches, and that a pad of antiseptic gauze and wool were applied as dressings. If, in an emergency, an Aveling's transfuser were not at hand, I should extemporise a pipette from a fine glass tube, and attach to this a piece of india-rubber tubing, using as an injector an ordinary syringe, or even a small funnel. A bulb blown on the tube forming the pipette would be a safeguard against the entrance of air into the circulation.

SOME REMARKS ON ABDOMINAL AND RENAL SURGERY.[1]

By Thomas Savage, M.D., M.R.C.P. Lond., F.R.C.S. Eng.,

surgeon birmingham and midland hospital for women; honorary physician magdalen asylum; consulting obstetric physician, kidderminster infirmary and birmingham lying-in charity.

The question as to the best method of treating fibroid or myomatous tumours of the uterus has long been before the profession, and is, at the present time, again assuming an important prominence. Years ago, before the development of abdominal surgery commenced, cystoma of the ovary and myoma of the uterus were often confounded together. Then, when it was found practicable for the cystoma to be removed by operation, attention was directed to myomata; and, from a commencing mortality of something like 66 per cent., hysterectomy has gradually advanced until it may now be considered at about 10 per cent. But, in addition, a great deal has been learnt about the nature and life-history of these tumours. At first it was thought that a woman, between thirty and forty, with a fibroid, although bleeding profusely, would be sure to get right at the menopause; and hence, little beyond rest, ergot, and such like remedies were used. It was believed that death due to hæmorrhage in such cases was almost unheard of; and many patients were doomed to pass through a prolonged period which, at the best, amounted to several, sometimes many, years of the greatest discomfort, debility, and inaptitude for either work or pleasure. If the tumour did, unfortunately, increase after the menopause, there was then nothing to do but to face the inevitable result with as much calmness and fortitude as could be possessed. We have changed much of this. We now know that patients do die from the direct effects of the hæmorrhage, and, indirectly, from other causes—*e.g.*, peritonitis and its effects, septicæmia, and the effects of pressure. And we have many resources at our command which we did not formerly possess. We now know that non-malignant uterine growths have two characters.

First, the soft, simifluctuating œdematous tumours. This form assumes a more or less large globular mass, involving the whole of the uterus uniformly, and has for its stalk the more or less stretched-out lower portion of the body of the uterus. These tumours are usually not characterised by hæmorrhage, and may attain very large dimensions; and they are less amenable to treatment. If the case demands so serious interference hysterectomy is, as a rule, the best remedy, and probably will be more successful than in the other class—viz., the second, or hard nodular fibro-myoma, in which the masses of tumour are arranged in separate portions, and may appear as sub-peritoneal outgrowths, or as sub-mucous growths, or may widen out laterally, in between the layers of the broad ligaments. These tumours are usually those which are characterised by hæmorrhage; and, by their irregular outgrowths in various directions, giving rise to troublesome pressure symptoms.

For the treatment of uterine tumours I would say, first of all, that very many patients, the majority in fact, do not require any special or heroic measures; rest, time, ergot, and such means will tide them over the space that intervenes until the menopause arrives, when the tumour will in all probability not only cease to grow, but will shrivel and very likely disappear with the general involution of the sexual organs at this period of life. But for those cases which are

[1] An address read before the annual meeting of the Shropshire and Mid-Wales Branch of the British Medical Association, June 25, 1889.

growing actively, where pressure symptoms are getting troublesome, where there have been attacks of localised peritonitis, or where hæmorrhage has become a symptom of importance by beginning to tell on the patient's health and strength, so that she does not get over the last period before the next comes on, it is necessary to do something more than temporise and trust to rest and medicines. For such as these there are three principal means at our disposal, and each has its place in particular cases. I refer in the order of their applicability to, first, removal of the uterine appendages; second, electrolysis; and third, hysterectomy.

First: Removal of the appendages has given most striking results, especially in the case of bleeding fibroids. If it is done early in the case, I mean when the appendages can be easily reached—*i.e.*, before the tumour has grown anteriorly or laterally so as to bury the appendages down behind it, low in the pelvis, it is an easy operation, and its mortality now is almost *nil*. After it the hæmorrhage at once stops, and the tumour thenceforth ceases to grow or begins to shrivel and finally to disappear. This is the remedy I should advise being tried first; then, if it had been found impossible to remove the appendages in consequence of the peculiarity of the growth, I would advise the use of electrolysis, according to the method of Apostoli. I have found that the application to the interior of the uterus of the positive pole, which is acid and astringent, has given great relief in arresting the hæmorrhage, and, so far, doing good. It is a remedy that requires much patience both on the doctor's and on the patient's part.

In my opinion, electrolysis is not to be condemned, on the one hand, with a mere shrug, as all rubbish and useless; while, on the other hand, I think some of its more ardent advocates are a trifle too enthusiastic about its potentialities. The application, by puncture, of the negative pole, which is alkaline, destructive, and hæmorrhagic, is attended with much more risk, and has given rise, in my mind, to some feelings of alarm. A patient with a very large tumour came to me in January last for abdominal section, because it was growing so fast. I could not reach the appendages, and I could not do hysterectomy either, because the lateral outgrowths were too broad to enable me to form anything like a pedicle. I therefore made an exploratory operation, and I advised her, after she had recovered, to try electrolysis with negative puncture. She had three punctures made at intervals of about a week; they were of about 150 milliampéres intensity, and lasted five minutes at each sitting. She was perfectly well in health when she came for the fourth application, which took place in due course; and she agreed to come again in ten days. As she did not come, I, in a few week's time, made enquiries, and found from her medical attendant, who originally sent her to me, that she had died on the twelfth day after the fourth application. He could give me very few details, scarcely more than that he had attended her for only about four days, that her temperature went up to 106°, and that her other symptoms were incessant vomiting, abdominal pain, and consciousness almost up to death. I concluded that this was certainly a case of septic peritonitis, and, in all probability, caused by the negative puncture. An unfortunate result such as the above is enough to make one pause before repeating the experiment, or, at all events, to make one look more deeply into the cause of the catastrophe with a view to prevent a recurrence.

Besides its efficacy, the safety of electrolysis has been lauded as one of its chief merits. The future will testify if this be so. All my other patients, upon whom I have practised electrolysis, whether positive or negative, have expressed themselves as having been benefited by the treatment. This must of course be taken for what it is worth.

Thirdly: If hysterectomy is performed and is successful, nothing can, of course, be more satisfactory or more brilliant. But the immediate risks from the operation itself are so great and formidable, that we are inclined at the present time to consider it indicated only if the patient's life is in danger, and other means, viz., removal of the appendages and Electrolysis have failed or are inapplicable. Thomas Keith, who has done so much to perfect the details of the operation, and who has had such eminently good results, has of late become a convert to electrolysis, and, in his recent writings, speaks as if it would be almost criminal to do hysterectomy; while electrolysis, with time and patience, will be all-sufficient to bring about the desired ends. For myself, I think there is still a field for hysterectomy.

With all the advantages that have been gained by surgery, up to now, in the range of the abdominal cavity, having attacked the liver, the kidney, and the intestines, it might almost be thought that we had reached a state of finality, in so far as this portion of the body is concerned. But is this really so? Is there not almost as much as ever to seek out in the surgery of the intestines? The operation for excision of pyloric cancer, and the creation of a gastro-duodenostomy has a good many difficult details connected with it, even now, which enthusiastic operators must set themselves to overcome. The recently adapted anterior colotomy, which is to supersede the old lumbar operation, shows that we are yet awhile far from having reached the goal of perfection.

Then, take the wide field of intestinal obstruction. It is doubtless a very grand triumph, that many cases of obstruction can be permanently relieved, and a few cured, by the operation of enterotomy; that is, by opening the abdominal cavity in the middle line, seizing the first projecting portion of distended gut, opening it and stitching it to the abdominal wall. By this means the dangerous symptoms are relieved by giving vent to the imprisoned fœces, and, as a consequence, in a few cases, the continuity of the intestinal canal has been restored. But we cannot, by any stretch of the imagination, look upon this as a perfect operation. It is certainly a good one, and by far the best that we have attained to; but we must admit, I think, that something less empirical, and something more scientific, has to be aimed after.

There are many details connected with the plastic proceedings in cases of fœcal fistula and excision of portions of intestine which have to be worked out; and there are many questions of physiological interest in relation to the liver; *e.g.*, when gallstones are large in size, why are they, as a rule, either solitary or few in number? or, on the other hand, why, when very small, are they sometimes very numerous? as in a case I recently had where they numbered 300. Then, in a distended gall-bladder, why is the fluid generally colourless or nearly so when stones are present, and often deeply bile-coloured or almost black when stones are absent? The operation of cholecystotomy is, as a rule, easy of performance, and is certainly one of the safest in the whole range of abdominal surgery; but very often difficulty may arise in the extraction of a stone, firmly impacted in the cystic duct, taxing all the resources of ingenuity and available appliances. Does gallstone originally form in the gall-bladder itself or in the hepatic ducts? I have noticed, in most of my cases, that the patients were in the habit of

going many hours without food ; thus giving rise to the view that during the periods that digestion was not going on the bile had frequent occasion to collect inordinately, to become concentrated, and to deposit cholesterine. But probably other changes in the bile of a chemical nature have been more efficient as causes.

The teaching in my earlier days was that gallstones seldom or never proved fatal; but I have myself, as I think most other practitioners must have done, found that this is not so. Patients do die from abscess, perforation, and obstruction of the intestines from an impacted stone. I have seen two of the latter cases in my own practice within the last few years. I consider that cholecystotomy should be more frequently performed : and I would go so far as to say that the propriety of operating ought to be considered in every case where the characteristic symptoms of gallstone are or have been recently present with persistent or recurrent jaundice, even if no tumour is to be felt ; but *à fortiori* if a tumour can be detected. The treatment of hydatid tumours of the liver is another phase in the same direction. The facility and safety of hepatotomy are about on a par with those of cholecystotomy, and the relief also is equally great and permanent.

I have experienced quite a number of instances of patients having abdominal tumour which presented such characters of hardness, immobility, and pain, attended with considerable and rapid emaciation, that it was considered beforehand, and reasonably so too, that a malignant growth was present. An abdominal section has been advised and the exploratory operation has revealed that the tumour was not malignant at all, but one which could be successfully treated and cured. This has been especially noticeable in cases of hydatids and distended gall-bladder. Such experience leads one to urge an exploratory operation being made even in the most hopeless looking cases. In the event of the diagnosis of malignancy being a correct one, there is at all events the melancholy satisfaction of being able to speak quite positively as to the nature of the disease, and the patient's life has not been shortened a single day by the procedure.

Quite recently a lady, æt. fifty-two, came to me with Mr. T. H. Ravenhill. She was emaciating, sallow in complexion, and had been for some months suffering severe and increasing pains. Per vaginam there were felt two hard nodules, very tender; one was behind the uterus, and the other was on the left side, not quite fixed but giving the feel as if it could be very slightly moved upwards. The case looked unpromising, and, in spite of the very slight mobility of the tumour on the left side, as if it were malignant. An exploratory operation was advised, and assented to ; and it was found that there were two sausage-shaped cysts : the left one was quite free, and the right one had become fixed by adhesion in consequence of a twisted pedicle, firmly down behind the uterus. This patient was cured by the operation. Another case was the hydatid tumour operated upon yesterday, a specimen of which is now going round. This woman came as an out-patient, and was a miserable looking object, thin, sallow, and dejected ; and it was thought that the hard nodule in the abdomen, between the sternum and navel, was most likely a cancerous mass. An operation was advised and carried out, with the result that about one and half pints of hydatid mass were removed, thus giving the patient a good hope of permanent recovery.[1]

[1] This patient has entirely recovered and is perfectly well.—T. S.

The organ which hitherto has proved to be least amenable to successful treatment by operation is the spleen. My own experience has not been favourable; and I confess I do not see much likelihood of any marked improvement. I imagine it is chiefly due to the fact that operation is not indicated, and therefore not undertaken, until the spleen has attained an enormous magnitude, and when the operation will in consequence be a most formidable affair. In addition to this, by the time the tumour is very large the patient has become reduced to such a condition of spanœmia and leucocythœmia as to be in state of health highly unfavourable for a major operation. So far very few of the completed splenectomies which have been done have been successful.

The remarks which I have to make on renal surgery are based upon the experience of twenty operations which have been performed by me ; sixteen of which were for removal of the organ. Of nephroraphy I have no personal experience, and I am inclined to think that the good results anticipated for it have not been altogether realised. It has been recommended for some cases of movable and floating kidney. It is a safe and easy operation.

Nephrotomy is advised for calculus in its early stage, before pyelitis and pyonephrosis have developed to any considerable extent. In a case where a stone can be extracted, the general secreting structures of the kidney being healthy, the result is brilliant and eminently satisfactory. But when calculous pyelitis has, in the course of time, developed into a large pyonephrosis, the kidney having become one large abscess-bag with very little true secreting tissue left, it would seem that mere nephrotomy is not enough, and that nephrectomy is a better proceeding. In such a case, if nephrotomy be done, the usual result is that a sinus, discharging a large amount of pus, is formed, which shows no tendency to heal : and from which the patient may eventually succumb. This occurred in one of my cases.

In addition, if nephrectomy has to be performed afterwards it is rendered more difficulty by the exudation into, and consequent density of, the perirenal tissues, the result of inflammatory products. I would strongly advise against tapping a pyonephrosis as a preliminary operation before performing nephrectomy.

Exactly twenty years ago, Professor Simon of Heidelburg performed nephrectomy for the first time, so far as is recorded ; and since then the operation has been performed many times both in this country and abroad, so that now it has become recognised as a most justifiable and useful proceeding. If the other kidney is normal, perfect health can be enjoyed after it, and the loss of the diseased kidney appears to have no drawbacks. The conditions for which it is indicated may be said briefly to be calculus, hydronephrosis, and pyonephrosis, malignant growths, *e.g.*, sarcoma, carcinoma, and tubercle, injury and rupture, and, in some rare cases, floating and painful kidney, when the trouble is so great as to interfere with the duties of life.

The operation is generally regarded as attended with much danger to life; but it is much less now than formerly. By some the mortality has been assessed at 46 per cent., but this is greatly in excess of what obtains at the present day. K. Thornton has had twenty-five cases with five deaths, or 25 per cent. I have done sixteen nephrectomies with two deaths, or about 12 per cent. Of the two deaths, one occurred in my second operation ; and I feel sure, with my present experience, that it would now have been

a recovery. It was a bad case of pyonephrosis, and death followed rather as a consequence of the operation not being performed in what would now be recognised as the best method, than as connected with the patient's condition. The second case was a man, worn down to the last stage of exhaustion with pain and calculus. Considerable venous hæmorrhage occurred during the operation, and death followed its completion in a few hours from shock.

The kidney may be removed by both the lumbar and abdominal incision. Each has some advantages in particular cases. In the lumbar operation the incision is the same as for colotomy, between the last rib and the crest of the ilium, and may be parallel to the former. The cases most suitable for it are those in which the kidney is not very much enlarged, and where a sinus exists. Among the advantages of this method may be mentioned that no important structures are cut through, that the peritoneum is not opened, and that the lumbar region can be easily drained afterwards by means of gravity and posture. Recovery is usually very rapid. The drawbacks are that the kidney may, from its great depth, be difficult to reach.

There is sometimes, especially in fat subjects, little space between the rib and the iliac crest, and it is of course impossible to ascertain the state of the organ of the other side. In one of my cases, where the pyonephrosis, although emptied of a considerable amount of pus, was very large, it seemed at one time as if the operation could not be completed; and I at length had to get the tumour actually delivered by pressure upon it from the front through the abdominal walls. Sometimes when the perirenal tissues becomes very dense from inflammatory exudation it may be necessary, in order to separate the organ, to extract the kidney by subcapsular enucleation. The pedicle is tied with a double silk ligature and divided. I had in my last case considerable arterial hæmorrhage after dividing the pedicle, although it appeared firmly encircled both before and after division. I could only account for it by supposing that there was some aberrant branch of the renal artery outside the ligature, for it was eventually stopped by securing a small artery, a ligature being applied to one small bleeding point. I should not like to trust the pedicle to a catgut ligature. Indeed, silk appears to be the best material for ligatures that have to be left behind within the body; it may not be so rapidly, but it is as surely, absorbed as catgut or silkworm gut. In one instance, where the pedicle was very short and thick, I deemed it advisable to use a transfixion pin with a Kœberle's serre nœud on its proximal side.

If the abdominal incision is preferred it may be performed either in the middle line, or laterally on the outer side of the rectus muscle. This is called "Langenbuch's" incision, and is much preferred by K. Thornton and some others. I find that in my series of sixteen operations the incision was made as follows: Abdominal six, viz., in the middle line four, lateral two; lumbar ten. In cases of large renal growth, large pyo and hydro-nephrosis, it is preferable to remove the tumour by the abdominal method. I believe I am right in saying that the late Dr. Alfred Meadows was the first in this country to perform nephrectomy in a case of large hydronephrosis, which had been mistaken for an ovarian tumour. In a case kindly sent to me by a member of this branch, Dr. Packer, there was thought to be present a large ovarian tumour. It turned out to be a very large hydronephrosis. Had I been a little more careful in taking the patient's history before the operation, I might have made a more correct diagnosis. There is a fear that, in the face of the present marvellous success of abdominal surgery, accurate diagnosis may sometimes not receive the amount of attention which is its due.

Each of the abdominal operations has certain especial advantages. With the lateral incision, both the kidney and the pedicle are easily reached by a cut through the posterior or external layer of the mesocolon, which has few vessels of importance likely to give trouble. On the other hand, as compared with the lumbar operation, there is the opening of the peritoneum, and the possible escape of blood, pus, or the poisonous contents of the tumour. With the central incision, it is easier to remove a large tumour, and to get to the pedicle to apply to the ligature; and an opportunity is given to ascertain the state of the other kidney. On the other hand the incision through the mesocolon is through its anterior layer, in which large vessels may be wounded. The possibility of a subsequent hernial protrusion may be noticed. Some operators have made much of securing the ureter separately, and leaving it outside, in the angle of the wound, to prevent the possibility of septic mischief arising from its presence in the pedicle within the abdominal cavity. I have not treated it thus, and have seen no ill result. Sir Spencer Wells has advised the making of a counter puncture through the loin for purposes of drainage, and then suturing the torn peritoneum, thus making the stages, subsequent to the operation, practically extra-peritoneal.

Although the immediate danger to life from the operation itself of nephrectomy for a floating kidney is very slight indeed by the lumbar method, the question must naturally arise, how far it may be justifiable to recommend so serious a procedure as the removal of a kidney for a condition which is not endangering life. A distinction has been made between "movable" kidney and "floating" kidney; and I take it that in the former the symptoms are, in addition to the palpable organ, general discomfort and occasional pain, which can be relieved, and sometimes cured, in course of time, by rest and the application of a pad, or other suitable support. Most of the cases of floating kidney can be relieved in the same manner; but I believe there is a rare case, met with every now and then, where the ordinary symptoms of dragging, sickening pains in the loins, nausea, occasional vomiting, diarrhœa or constipation, frequent micturition, depression of spirits, and consequent general debility, are much aggravated, and the pain is either constant or comes on in paroxysms of such severity as to completely unfit the patient for the duties or enjoyments of life; and in such as these I believe the operation is indicated. My last nephrectomy was such a case. It occurred in the person of a young lady, æt. twenty-two years, a governess. For some two years she had had constant pain, which neither rest nor support relieved, and for the last six months she had, in addition, almost daily paroxysms of pain, which at length compelled her to give up work. The operation and its effects were pointed out to her and her friends, and she elected to have it done, with its risks, etc. She preferred to go through life with one kidney, rather than have two and continue as she was. From the moment of the operation she felt no pain whatever. I was associated in this case with Dr. Marriott, of Leamington, and Dr. Haig, of Coventry.

It is not easy in every case to say to what cause the pain is due. It has been ascribed to the stretching, by the elongated mesonephron, of the renal and solar plexuses; and also, I

think by Dr. Alexander Simpson, to a kink in the ureter. I believe that the presence of a movable kidney is much more frequent than we are apt generally to suppose. It has been said that, if we take a large number of patients, one in every 250 will be found to be so afflicted. What influence child-bearing and tight-lacing, the two most frequently alleged causes, have in producing the condition we are not at present in a position to say. For some cases of intractable nephralgia, Dr. Tiffany, of Baltimore, has recently recommended free division of the capsule of the kidney; but I am not acquainted with what results this novel practice has been attended.

As a result of removal of one kidney, there is naturally to be expected a condition of hyperæmia of the other organ; and this is not unfrequently manifested by the presence of some degree of hematuria after the operation, and sometimes of some albumen in the urine, both of which may persist for some weeks. I have thought it wise in such cases to restrict the amount of nitrogenous food, in the shape of meat, which should be taken during the continuance of this condition of things.

ON THE TREATMENT OF FRACTURES OF THE PATELLA.

By Hugh Owen Thomas, Liverpool.

A reader of our various medical periodicals issued during the last ten years must have noticed the great interest surgeons have taken in the treatment of fractures of the patella. They will have further noticed the frequency with which those who have discussed the subject recommend operative interference, and the dissatisfaction expressed in regard to the efficacy of past treatment. In October, 1882, I contributed an article, which was published in the *Medical Press and Circular* of that date; it was a sketch of a new departure, well tested, in the treatment of fractures of the patella.

Although seven years have since passed, there has not been published any evidence confirmatory of the value of my advice. Seven years of added experience in addition to that of surgical acquaintances and neighbours, is in favour of the teaching which I laid down in 1882. If the question was put to me: "Of all the important fractures presented to the surgeon for treatment, which of them is the easiest to restore and repair, and least cripples the patient during treatment?" my answer would be: "Fracture of the patella," and that for the following reasons: If the injury be a simple fracture, the result of muscular action, the patient may return to his work as soon as the surgeon has applied his skill. If it be a simple fracture from direct violence, with much intra-articular effusion, then the sufferer is ready to go about as soon as the effusion has been absorbed. If it be a compound fracture, the case, though still easily restored and repaired, by reason of the cutaneous complication, requires that the patient should rest until the wound has healed; then, whether that period be short or long, the patient leaves bed, and resumes locomotion. This prognosis is made upon the supposition that the surgeon in control of the case practises the indirect method of fixing the knee-joint exactly similar to the plan introduced by me to the notice of surgeons, as proper for the treatment of knee-joint inflammation, a rough sketch of which is shown in the accompanying woodcut. This I find to be a much superior plan of carrying out the indirect method than the one I published in 1882.

During the many opportunities I have had of treating these accidents I have gradually attained the conviction that neither position nor nicety of adaptation during treatment is in any way essential to a good result. What we want is a method of treatment which renders nearly certain a recovery of the knee-joint free from defect in function.

Experience has clearly taught me that there are four points hitherto overlooked, which, if attended to, give success. The first is time; the second, non-interference with the circulation around the patella; the third, that no strain in the direction of flexion be allowed during treatment; and lastly, that the temporary stiffness produced by the treatment should be allowed to pass away spontaneously. In regard to time, I now know that it is necessary to postpone, uninterruptedly, genu-flexion until a period of five or six months has elapsed. This is the time which observation has indicated to me as the safe date at which to suspend control.

The months of surgical control may be considered as divided into three periods: the first representing the removal of effused fluid; the second during which union is progressing; the third being spent in the consolidation of the uniting medium when it becomes free from inflammation—*i.e.*, healthy. At the end of this third period the connection between the previously separated segments of patella—whether bony or ligamentous—will withstand, if sound, any habitual strain, and whether the two segments have been in close opposition or a perceptible distance apart, is merely important from the point of view of appearance. As an example of the efficiency of the indirect method of treating these fractures, I place before the reader a few short notes of cases:

Two months ago, on a Sunday evening, I received a message to visit a lady with a fractured patella, at the north end of the town. My reply to the messenger was that the lady should be brought to my surgery. In two hours she arrived in a cab, with great commotion. Several friends assisted the patient into my surgery, where I at once fitted her with a bed knee-splint, then screwed a tube heel-plate to the shoe, and as my blacksmith was not at home, with the aid of my steel vulcan fitter, I cut the bed splint into a calliper to fit into the heel-plate of the boot, completed the fixation in accordance with the indirect method—the whole procedure occupied about half an hour; after which the patient walked out of the house into the cab, and went home. Passing her residence some days afterwards I visited my patient, and found her in the kitchen attending to her household duties. It was fracture produced by muscular action, and at this date, two months after the accident, the contact of the fragments is perfect, but treatment has not yet been suspended.

Three months ago, on another Sunday evening, I was interviewed by a messenger, who requested me to go to Hill-street and attend to a fractured knee-cap. I instructed him to bring the patient down to my surgery the next day. He was assisted out of the vehicle in which he was brought, but after a delay in my surgery of half an hour, and the application of the indirect method of fixation, he walked home, with the assistance of a walking stick. This was a case of fracture from muscular action.

About nine months ago, late in the evening after my hours of consultation, there drove to my door, from Runcorn, a covered waggonette. In a few minutes afterwards a patient was carried into my surgery, by several men, whom I found to be suffering from a fractured patella, caused by muscular action. Unaided, except by the Vulcan fitter, the fracture was fixed by the indirect method, and in half-an-hour the patient walked out into the waggonette and, with his companions, drove merrily away, and returned in a fortnight for my inspection. Afterwards he came every three or four weeks during a period of five months, at the end of which time the treatment was suspended, and the restoration and repair were found perfect.

Two years ago I proceeded to the Principality to visit a gentleman who had been confined to his room for two or three weeks suffering from a fractured patella. The cause has passed out of my recollection. Assisted by Dr. Owen, of Beaumaris, we fixed the fracture by the indirect method, and at the termination of the operation the surgeon, patient, and myself went downstairs and enjoyed dinner. From that moment until his recovery he was able to resume his duties, those of commander and navigator of a large steam yacht. The repair in this instance was perfect.

Another illustration: Some two years ago, in consultation with two other surgeons, we examined a gentleman residing about twelve miles out of this city, who suffered from fracture of the patella, the result of direct violence. The injury was followed by extreme effusion within the joint, and the surgeons had very wisely, considering the extreme degree of capsular distension, confined the patient to his bed. At the time we examined him the effusion had been nearly all absorbed. We agreed that the next day the fracture should be treated by the indirect method of fixation. After we had carried out this agreement perfect repair followed in due time.

Still more clinical evidence: I assisted Dr. Evans, of Waterloo, to fix, by the indirect method, a fractured patella. A fortnight had elapsed between my visit and the accident. Three days after our consultation the patient did shore duty as assistant steward at the docks. The cause of the accident was muscular action. The result of the treatment was perfect restoration. Nine months after recovery the same man drove up to my house in a cab, having injured his knee by slipping in the street. On examination I found that he had re-fractured the patella. With Dr. Evans' concurrence he was re-fixed according to the indirect method. Again, after being fitted with the appliances, he walked away, and revisited me in about a fortnight's time. After examination I informed him that the knee was progressing favourably; he replied that he thought so, and added that he believed that he could manage the case himself, and would not call again, which resolution he adhered to, as we did not see him again. This is the only drawback I know that is attached to this method.

Further illustration: Accompanied by a medical friend, I drove eight miles out of town to visit his patient, who suffered from a fractured patella. On being introduced to the patient, I recognised a gentleman whom I had treated for a similar accident fourteen years previously. He was treated on that occasion according to the then standard method. On the present occasion an innovation was practised; the fracture was fixed by the "indirect method." After we had finished the operation the patient inquired, "How long do you think I shall be kept away from business?" My reply was that he might leave his residence next day and superintend his business. He appeared surprised, and remarked, "that will never do, I am insured against accidents." I then advised him to be guided by his usual medical adviser. The case resulted in perfect restoration and repair. Five years ago a physician, in this city, requested me to visit one of his patients residing in Upper Parliament-street. On my arrival at the house I found an elderly gentleman, seventy years of age; he was in bed with a fractured patella. He was at once fixed up by the "indirect method," and the following day got out of bed, and continued to do so daily until he was perfectly restored and repaired.

Last year, a message was delivered to me from Daulby Street, requesting me to visit a gentleman who had broken his knee cap. Accompanied by Dr. Lewis, of Kansas, U.S.A., I visited the sufferer, whom we found in bed incapacitated by a fracture of the patella, from muscular action. Assisted by Dr. Lewis, and employing the "vulcan fitter," we converted a knee bed-splint into a calliper, then applied a tube heel plate, and fixed the fracture by the "indirect" method, and got the patient out of bed. He remained in the house a week, but being an elderly person, over sixty years of age, he seemed to be short of reliance upon his fixture; nevertheless, at the end of a week, he went daily to business, which he conducted upon the other side of the river. The restoration and repair were perfect. I shall only trouble the reader with one more example. Three years ago, accompanied by a surgeon from Boston, U.S.A., I went to show him a case of fractured patella, which I had fixed by the "indirect" method two days previously. On arriving at the house, we were informed (it was late in the evening) that the patient had not yet returned from his work, which was that of foreman engine fitter. The history of the case is as follows: two years previously I had attended him with fracture of the left patella, and treated it by the "indirect" method, with the result of perfect restoration and repair. The second accident was a fracture of the right patella; both injuries resulted equally satisfactory. During the first injury, he remained in the house a week; during the second, at my urgent request, he resumed his duties the day after the accident. Such was and is my confidence in the "indirect" method of treating fractures of the patella. The question might reasonably be asked: "What degree of approximation of fragments was apparent after recovery from this injury when treated by the "indirect" method? The correct answer to such a question is this. "A perceptible space is a very exceptional result." During the treatment, especially those cases resulting from direct violence with great tensile effusion within the joint, the surgeon should then enjoin a week or a fortnight's rest in bed, but at the earliest possible moment the patient should be ordered out of bed and employ his limb in locomotion, so as to produce a tense, brawny œdema external to the joint, the formation of which the "indirect" method generally favours, and upon which œdema the surgeon has to depend *entirely* for maintaining *perfect* opposition of the patellar fragments. The surgeon may occasionally be called upon to manage fractures of the patella unavoidably neglected, with much separation of fragments and defective power arising therefrom. This phase of the question has already been discussed by me in Contribution VI., "The Principles of the Treatment of Fractures and Dislocations," and I purpose re-opening it in a subsequent number of this journal.

A NOTE ON THE TREATMENT OF CLUB-HAND.

By Robert Jones,
HONORARY SURGEON TO THE LIVERPOOL STANLEY HOSPITAL.

The condition known as club-hand has proved a source of much practical difficulty to many orthopœdic surgeons, some of whom do not hesitate to recommend amputation in those cases which they consider sufficiently severe to resist all treatment. Most, if not all, regard tenotomy as very frequently indicated, and very often render this operation so complete as to sever nearly all the flexors of the wrist. The severity of the latter procedure becomes more evident when we recollect the intimate situation of the wrist tendons, and the risk, so often occurring after operation, of adhesive inflammation and consequent interference with the proper play of the fingers. My experience has been so free from anxiety in the treatment of this lesion, that some good may take place by briefly stating the principles, simple as they are, which should govern our manipulations.

I have seen more cases where the flexor muscles are shortened, and the palmar surface of the hand is flexed on the forearm, and I will first allude to the treatment of such. The sooner treatment is commenced the easier becomes the surgeon's task, and I have treated infants only seven days old. The hands should be held by the surgeon, and gently stretched every morning for some days, the severity of the stretching to be gradually intensified until extension can be made by the hand without any great force. I next place in each of the infant's hands a small wooden bar, allowing the fingers to curl over it—grasp it in fact. Bandage is then used to hold the bar in position, and should be re-adjusted every one or two days according to the severity of the grip. In a fortnight or three weeks, providing good progress is being made, I turn my attention to the wrist, and having removed the bars from the hand, place the forearm in a splint so constructed as to gradually straighten the hand and wrist. This is best attained by employing a zinc or sheet-iron splint which the surgeon can from time to time bend. Flexor massage may now be employed either by means of thumb pressure along the separate muscles, by friction, or by flaggelation. The hands should next be placed in full extension, and the splints modified, so as to admit of maintaining them in the extended position. This is practically the last phase of treatment, and the hands should be maintained in this position until all tendency to contraction has ceased. This may take a great many weeks, but in my experience always occurs. By this method the lengthened extensor muscles become shortened and the flexors stretched, and the muscular equilibrium become more directly restored than any other treatment will admit of. In the present brief note it is not my attention to give cases, but rather to point in a general way to a safe, easy, and efficient mode of dealing with a condition which is supposed to be surrounded with difficulties.

HEALTH RESORTS OF THE WORLD.

XXXIV.—WEYMOUTH.

By W. Armstrong Willis, Monmouth.

The very name Weymouth, to most readers, has an aroma of old world wholesomeness and memory in it. It seems just the place where the eighteenth century feeling its end at hand, and grown weary of the routs, concerts, bell-ringing, assemblies, and general modishness of Bath, seeks a fresher and more austere spot, there to renew its youth and gather strength from its breezes, and so prepare for the full expansion of the nineteenth century and Brighton. All reminds one of George III, and while the eye rests with pleased amusement on the would-be classic frieze of an old mansion (apparently representing festoons of white towels on a back-ground of pale jasper-blue), the mind is busy at work repeopling the place. Chief of the ghosts of the past are the Farmer King and his little, homely-looking Queen; following, come that wonderful family of handsome sons and daughters, said to have been, when together, the best looking family in Europe. More than all of them does one see the Princess Amelia, the youngest of the six Royal daughters, the favourite of the King, and who died at the early age of twenty-seven of consumption. Indeed it was from Weymouth that she was brought home in 1810 to Windsor to die, and it was her death which plunged George III. into his final attack of madness. There is nothing more pathetic in English History than the grief of this poor father for the loss of his charming and devoted daughter. Her eldest sister, the Princess Royal, afterwards the Queen of Wurtemburg, thus wrote of her: "Poor dear Amelia has had a long and painful illness. She is a sweet, amiable, pious, good little soul; patient beyond description, and has the greatest resolution and fortitude. She is a perfect example. I never saw so good a disposition; so thoughtful and considerate to those about her; so afraid to fatigue them by sitting up with her. I never saw anybody more careful to disguise her sufferings for fear of vexing others; and truly it is most vexing to see her in such a state of health." How sweet a character this unaffected letter depicts, and how hard to realise that the Princess Amelia was wholesister to the Regent. However, it is with the present and not the past Weymouth that we are concerned; it is well to remark that no place lends itself less easily to the daubs of the "word painter" (one of the worst of the tribe of modern bores). Some have asserted that the great Bay at Weymouth is like the Bay of Naples. This comparison is as truthful as that of the Wye to the Rhine, or of Saint Paul's to Saint Peter's. There exists the same likeness between Weymouth and Naples as between a portly and respectable town counsellor of the one place, and the most sun burnt of the red-capped lounging Lazzaroni of the other. In fact nothing more essentially English than Weymouth can be imagined. The great sweep round its bay, of solidly built, plain lofty houses; the good masonry and fine roads, the complete absence of all noisy gaiety; in fact the general seriousness of Weymouth all protest loudly against linking it, for a moment even, in association with the garish southern brightness of Naples. It is unnecessary to point out how silly are these so-called comparisons of widely differing places. Sad though it may be to miss the light, the warmth, and the colour of Italy, yet there are many among us who find compensations, such as the absence of vermin, beggars, fevers, and general shamelessness, all of which, alas! are too well known in the Bay of Naples the Beautiful. Weymouth is most pleasantly clean and bright, and shines with that brightness which comes of the cleanly habits and good sanitation of our self-respecting Anglo-Saxon race. Lodgings here are abundant, cheap, and close to the sea; the sea itself is magnificent for bathing, and ancient mariners abound who take one out for a sail or a fishing expedition, and out of their vast store-house of memory or imagination can pour forth strange stories of old smuggling days. To

one anxious for sea-side change and liking all the solid comfort of a good town, yet perhaps unwilling or unable to afford a fashionable, crowded health-resort, this seems the very place. There exist now so few places occupying a position half-way between the noisy crowded rising or risen watering-place, where lodgings are dear, houses too often new and ill-drained, and everything sacrificed to appearances on the one hand, or some rough half civilized place on the other, which is simply cheap because one has to deprive oneself of most of the things that make life bearable. Again, if tired of Weymouth, there are few neighbourhoods more interesting or more abounding in note-worthy spots. First, of course, comes the Isle of Portland. Without entering into its characteristic geological formation, which well repays observation, it may be mentioned that Portland contains two most striking objects; one is natural, the other the works of mens' hands, and most unwilling hands too. These are the immense breakwater constructed by convict labour, and the Pebble Ridge called Chesil Bank, which in truth makes the island a peninsula and connects it with the Abbotsbury coast. This beach is two or three miles long; its usual height about forty feet; its thickness about 200 yards; at the Portland end it is composed of pebbles, worn smooth by the action of the waves and weighing several pounds. These pebbles imperceptibly diminish in size till at Abbotsbury they are small gravel; and at Burton Bradstock finally small sand. Chesil Bank is one of the most imposing, bleak, barren, natural ramparts that the mind can conceive, and a walk of a mile along its grey crest would be a fresh torture worthy of the Inferno. Standing on this beach looking up at the island one feels fascinated by the utter dreariness of the scene. On a day with a grey sky, the great piles of grey cliffs, the strangely bare-looking grey houses creeping in one steep street up the sad-coloured hill all present a picture in mourning tones of grey which might inspire Mr. Whistler for a fresh "harmony," and form no unfitting setting for the dreary lives of the convicts. But there is the more hopeful and cheering reflection that genius has out of the dull rocks of this Isle of Crime created many a noble pile, and the stones of Saint Paul's could they but cry out might tell us they had come hence.

The breakwater was begun in 1847, and consists of two great arms. One of them is connected with the mainland and runs out to sea about 1,800 feet; then an opening is left for ships, 400 feet wide; and beyond this the great main breakwater stretches 6,000 feet in length. As all these great works are of Portland stone, it may in a manner be said that the island has been partially destroyed for its own protection. In nooks and crannies rare plants may be found, and the Portland spurge is not extinct. Leland, in in the course of his Itinerary over all England in the time of Henry VIII., gives a quaint account of the place and its then inhabitants, which may be quoted with a few slight omissions without apology. "Portland (he says) has been of auncient tyme by all likelihood environid with the Se, and yet berith the name of an isle. It is eminent and hilly ground on the shore of it, and a great plain in the middle of it. The cumpace of it is counted to be about a seven miles; but if a man should cumpace it by the very rootes and depe shore would mount to a ten miles. The soil is somewhat stony, and the shore very rokky. The isle is fruitful of corn and gresse, and hath plenty of sheepe. Ther be at this present tyme about an eighty housis in the isle. Ther hath been almost as many mo, as it apperith by the ruines. Ther is but one streat of housis in the isle; the residew be sparkelid. There is a castelet or pile not far from streate, and is set on a high rokke, hard by the se cliffes, a little above the est end of the cherch. The paroche cherch (that is but one at this tyme in the Isle) is long and somewhat low, buildid in the hangging roots of an hill by the shore. This cherch and paroche is about a mile dim: to go the next way to it from the Kinge's new castelle in the isle, and to go to it by cumpace of the shore, it is three miles or more. Ther be very few or utterly no trees in the isle saving the elmes about the cherch. Ther wold grow more if they were there plantid; yet is the isle very bleke. The people bring wood thither out of Wight and other places. They brenne also cowe-dung dryed with the hete of the sun. The people of the isle live most now by tillage, and sumwhat faulle from fishing. The people be good there in slynnging of stonys, and use it for defence of the Isle. They be politique enough in selling their commodites, and sumwhat avaritiose. The isle is the Kinges; and much of the land there is holden by hym." The new castle which Leland alludes to still stands near the landing place of the Weymouth steamers, and is now used as a modern residence. In every other respect Leland's Portland is utterly a thing of the past. From Weymouth excursions can cheaply and easily be made to Dorset, with its Roman and pre-historic remains and new County Museum; to Corfe Castle and to Wimborne with its splendid minster. Christ Church, with its beautiful priory sleeping peacefully in meadows worthy of Arcadia, on the banks of the widening Avon, is also easily accessible, and contains a monument to Shelley, whose ashes were, however, long ago gathered from the funeral pyre in the Gulf of Spezzia, and placed in the Protestant Burying Ground at Rome. These old southern towns are full of interest. They often contain quaint gems of old street architecture. For instance, Poole on the border shores of Hampshire and Dorset, though it contains no building of great historic interest, has streets and corners and alleys full of old houses of the most varied types; from the fine red-brick Queen Anne mansion with its ample perron and great coat of arms blazoned in Chippendale style over the middle of the frontage, back to every kind of quaint gable, bow window, and over-hanging eaves.

Another easy excursion is to Bournemouth and its pine trees and fine sands; its winter and spring crop of exclusive invalids, and its summer crop of rudely healthy visitors, are a widely differing but noticeable feature. In the winter one sees worthy bronchitic Bishops, Deans, and Dignities; in the summer tribes of jolly-looking children and their slaves (parents and nursemaids). With Weymouth as head-quarters if the sea be tempting, weather fair and winds favouring, what can be pleasanter than to steam off and see the Channel Islands? Even if no stay be made there, the beautiful scenery of the coasts of the islands, the deep blue and purple of the sea, and the fruits and flowers of Jersey will more than repay the slight discomfort of a steamship, and the trip will be a cheap one. In spite of the thousands of tourists, both English and French, who now through the summer and early autumn months flock to Jersey and Guernsey, many a quiet lovely spot may be discovered, where a pleasant few days may be passed, and nowhere so close to the shores of England do you get a sea of such colours as off Jersey, often approaching those of the Adriatic.

But if the Channel Islands are lovely, the scenery, too,

of Dorsetshire is attractive owing to its constant contrast. There are regions in high cultivation often surrounded by the wildest and most barren heath and moorland. You may stand as on the edge of the great ancient British Agricultural Camp of Dudsbury, between Wimborne and Bournemouth; at your feet the Stour with its white and yellow water-lilies, gliding placidly between reed and sedge-laden banks through the richest and most fertile of meadows. A rich haze hangs over the distance even on the finest day, and mellows and idealizes everything, till the many-arched bridge of Longham seems of classic construction, and you have a picture of Claude's on which to feast your eyes. You turn your back on the Stour, and there for twenty miles and more you have the wildest and most dreary moor scenery. A great barren heath, with a few scattered mounds in the foreground, the burial place of some old heroes of the Durotriges probably. Here the cotton rush, the yellow asphodel and bog myrtle flourish among gorse and heather, and the great heath melts away into the blue distances of the New Forest. It is hard to realise that close to so many towns there can be this great desolate stretch of moor; but the contrast it affords to its fertile surroundings of tranquil pastoral landscape is very typical of one aspect of Dorset scenery which mingles the "blasted heath" of Macbeth with the Vale of Tempe.

These, I think, are no mean catalogue of attractions in and around Weymouth. Of course there are many more, but they would swell the bulk of this article unduly, and the intention was only to dwell on more salient points. One can truly add that for sea, air, general healthiness, and interest of surroundings, one of the deservedly best health resorts in England is Weymouth.

A VISIT TO THE WORKS OF THE SANITAS COMPANY.

By a Quondam Medical Editor.

Perhaps no question concerns the world at large more deeply than the causes of the healthfulness of one locality, and the dangerous character of another. I do not think that it is any explanation to be told that the latter may be or is due to malaria. That seems to amount to nothing more than this—accounting for disease by a fanciful hypothesis. No doubt it is very convenient to talk of malaria, but what do we know of it—its causes and remedies. I may be showing my crass ignorance of the whole subject when I say that malaria seems to me a convenient term to describe or convey unhealthiness. Once in the Southern States of America a physician of repute explained to me that malaria was only another name for a blue fog that was confined to certain localities, and generally rose to a height of four feet or so. This was fresh to me, and now I never think of malaria without picturing a blue fog to myself.

Whatever may be the explanation of the dangers surrounding residence in certain districts, I will leave to others; but the health-giving properties of the air near pine forests have long been beyond question. Daily increasing use is being made of their invigorating and restorative influences on persons liable to lung and throat affections. In America, summer parties are often, it is said, formed to camp out in the pine woods, while the pine groves of Weybridge, Bournemouth, and Arcachon are familiar instances, closer at hand, of the efficacy of this class of vegetation in promoting health. The recklessness—I can use no other term—with which the pines are being mown down at Bournemouth, is much to be regretted, and must before long diminish the value of a visit. The eucalyptus globulus, or blue gum of Australia, is another and more recently discovered tree having much the same properties, and its salubrious influence in softening the air is now generally admitted. This tree has of late built up a great reputation for making localities habitable, which were previously seats of malaria, or at any rate of disease. In Algeria and in Portugal, too, there are valleys which were a few years ago most unhealthy, but which have now become healthy by planting this tree in them; while another still more striking example of its fever-correcting properties is found in the re-occupation of a deserted cluster of monastic buildings, three miles from Rome, in a most desolate part of the Campagna. This was effected by some Trappists, who planted, several years ago, eucalyptus groves. For centuries the fever-stricken monks had vainly battled against malaria, and at the close of the last century the monastery had to be abandoned. Although the remarkable efficacy of the eucalyptus globulus and the pine in preventing disease and preserving health has been thoroughly recognised, the connection between cause and effect has only recently been clearly established. The clue to the connection has now been ascertained beyond all cavil, and as a result of the discovery we have had an important addition to the long list of antiseptics and disinfectants under the title of "Sanitas." This discovery was not the result of direct inquiry, although the fruit of a purely scientific investigation of a cognate character, in which Mr. C. T. Kingzett, the distinguished chemist, was for years engaged. Engrossed in an exhaustive enquiry into the nature and action of ozone, which till recently was supposed, and it seems erroneously, to be nature's great purifying agent, Mr. Kingzett tried to satisfy himself that its presence in the atmosphere was due, as was generally supposed, to a process of slow oxidation of the essential oils or perfumes which are given out by strongly odoriferous plants when freely exposed to the air. But no satisfactory proof of the production of this active principle was forthcoming, and Mr. Kingzett ultimately concluded that these plants did not evolve ozone, but peroxide of hydrogen. Working at this hypothesis, he went on to establish its correctness by a laborious series of experiments, and at last completely succeeded. He submitted a large number of oils, and other likely bodies to the action, under various conditions, of atmospheric air, and found that they all rapidly absorbed oxygen, the gas entering into combination with them and forming new bodies. This property of absorption was, he found, possessed in far higher degree by turpentine than by any other of the many substances tested. He also ascertained that when turpentine was exposed to a current of air in the presence of water, at average summer heat, oxygen was absorbed, and the oil was oxidized, a compound being formed which was unstable in the presence of water, and which split up into peroxide of hydrogen, a peculiar soluble camphor, and camphoric acid. The conclusion he came to was that the hygienic peculiarity common to pine and eucalyptus groves was the evolution of these three substances, and the cause of their production was atmospheric oxidation of the naturally secreted oils which are volatilised from them. This natural process of oxidation takes place in any essential oil containing the chemical body known as "terpene"—the principle of turpentine; this curious substance is common to all these odoriferous plants, but is most powerful in the pine-produced turpentine of commerce. Having made this brillant discovery, Mr. Kingzett's next aim was to

imitate in the laboratory the results produced on a magnificent scale in nature. He had shown that the health-giving atmosphere of the pine wood or the eucalyptus grove was due to peroxide of hydrogen and to the camphoraceous substances produced by the resinous oils secreted by those trees; he had proved that these invaluable natural purifiers could be obtained from common turpentine, and he had now to manufacture them in such form and on such a scale as would make them useful to the general community as antiseptics and disinfectants.

Here I must mention that Mr. Kingzett does not claim to be the discoverer of the disinfecting properties of peroxide of hydrogen, for they have long been known, although the preparation of this powerful body had hitherto been too expensive to admit of its being used for ordinary sanitary purposes. What Mr. Kingzet takes credit for, and I believe justly, is the identification of its purifying power with part of that of the pine and the eucalyptus, and the perfecting of a method of manufacture which enables the artificial substance, in association with other equally valuable bodies, to take its place as a commercial article. In bringing his method into practice, Mr. Kingzett associated himself with Mr. M. Zingler, and these gentlemen carried on a series of manufacturing experiments and devised plant, which they perfected slowly and laboriously, until it was finally brought to the successful point at which I found it a few weeks ago, when I saw it at work producing "Sanitas" fluid and oil on a very large scale.

The works at which these fluids are made are in Three Colt Lane, Bethnal Green; they have been, from time to time, visited by many investigators of considerable eminence in different departments of science and hygiene, and the description of the process as seen by them will serve my present purpose. There are, in the first place, two large boilers furnishing low-pressure steam to work a double acting air-pump, and the latter, in case of necessity, can be replaced by another engine constructed on the principle of a Roots' Blower. The air current thus obtained is passed, under pressure, into an air box and as a result of this its temperature is raised to a point corresponding to that of the mixture through which it is subsequently pumped. In line with the air pump are many rows of wooden vats, each vat contains an earthernware vessel or producer, about three feet in diameter and four feet high: these are immersed in the vats in water, and are kept at a temperature of about 60° C. These producers are charged with 100 gallons of a mixture of water and turpentine, or camphoric oil, or eucalyptic oil, whichever chances to be most handy. Over the producers runs an air main from the blower, and from this a branch pipe passes into each vessel, ending at a junction of the turpentine and the water. The blast of hot air is introduced into the turpentine, and gradually oxidises the latter and makes it also throw down into the water, certain of its constituents in combination with the oxygen of the air. In course of time the turpentine is thoroughly oxidised, although for that purpose the process has to be carried on a long time varying from 50 to 300 hours, according to the quantity of the essential oil employed and the required strength of the products. When the process is completed, the aqueous residuum in the vessel is drawn off, and this residuum is commercial "Sanitas" fluid, the form in which it is bottled for the market, and following it, comes the oxidised gold coloured body known as "Sanitas Oil."

In the course of this prolonged oxidation the turpentine or other hydro carbon, which is used, forms by its rapid absorption of atmospheric oxygen a peculiar chemical principle named by Mr. Kingzett, camphoric peroxide. This substance is the chief constituent of "Sanitas Oil" and is present in such amount that while a gallon of raw turpentine weighs 8.65lbs, a gallon of oxidised "Sanitas" oil weighs from 9.5 to 10 lbs.

In contact with water, this camphoric peroxide is decomposed and gives rise to the production of peroxide of hydrogen, camphor, camphoric acid and other substances, which are dissolved in the water. It is in this way that the water, which is associated with turpentine in the process described becomes converted into "Sanitas Fluid" In addition to the other constituents of this liquid, mentioned above, there is thymol the antiseptic properties of which have been thoroughly recognised and investigated.

As the process of manufacture goes on, the air, which has parted with a large portion of its oxygen to the turpentine, takes up some of the latter, and this has now to be recovered from it; this is managed by causing the turpentine laden air to pass through a series of earthenware jars constructed on the principle of Wolffs' Bottles, in which it is washed with successive quantities of water. In its passage through this apparatus the turpentine condenses and floats on the surface of the water in the Wolffs' Bottles and is afterwards returned to the producers, so that no waste is permitted in any stage of the manufacture.

With respect to the purposes to which "Sanitas" is applicable, we must say a few words. Not the least important, from an economic standpoint, is the preservation of food. It also occupies a very high position as a disinfectant, for while pleasant to use, it neither injures nor stains textile fabrics, nor is it poisonous, and as far as is known very large quantities of the fluid can be swallowed with absolute impunity: in these respects it completely differs from carbolic acid, sulphuric acid, the permanganates, coal tar substances, and other common disinfectants, which are either extremely poisonous and often lead to the destruction of human life or are so objectionable in other respects as to limit their employment. These advantages have been thoroughly demonstrated and highly favourable opinions as to the merits of "Sanitas" products have been given by Sir H. E. Roscoe, M.P,, F.R.S., and by hosts of other eminent scientific authorities. In short, a very brief trial is sufficient to show the value of "Sanitas," which has now taken its place as the most popular antiseptic and disinfectant in the world, and the consumption of which is increasing with such rapidity that at times the resources of the manufacturers are strained to the uttermost to satisfy the general demand.

The factory in which the process of manufacture is conducted is large and well arranged, and with scrupulous regard to the health of the staff; and Mr. Kingzett told me that the death and sick rates were low, and that the workpeople were singularly free from many common diseases. The factory contains a great number of huge receivers connected one with another; and, by the way, as the operations of the company are now on a colossal scale, and are rapidly increasing, it has been thought prudent to have the machinery and the receivers in duplicate, so that should anything go wrong with one set the operations would not be at a standstill. In other departments the manufactured products are, in due course, mixed

and prepared for use in a bewildering variety of ways. In combination with precipitated chalk an excellent tooth powder is made; manufactured into soap "Sanitas" is economical and agreeable. Preparations are also made for washing wounds, instruments, and hospitals, and its consumption in midwifery practice is now large; while among other notable products is Sanitas-sawdust, which is used for sprinkling in poultry runs. It is said that when regularly used in this way disease is unknown, so that there is likely to be a large consumption of it in yards and runs of limited extent, where, as poultry fanciers know to their cost, disease is apt to arise after a time and to kill off the stock. Another liquid known as "Crude Sanitas" is prepared for street watering in hot weather, and for the disinfection of drains, sewers, ash-bins, slaughter-houses, and, indeed, of all offensive places generally.

Among the most curious things shown me were a couple of glass vessels in which mutton chops and beef steaks had been immersed in Sanitas fluid, and had been preserved for eleven or twelve years; these chops and steaks still retain their freshness and firm, characteristic texture. However, we are afraid that no future awaits pine products as food preserving agents, for, unfortunately, a very characteristic odour is imparted to the meat, which unfits it for human consumption. The "Sanitas" disinfectants—fluids, powders, and soaps—are now used by most public health authorities and hospitals in this country, and Mr. C. T. Kingzett is to be congratulated on having overcome the difficulty and opposition, which always beset the scientific investigator who attempts to carry into practice on a commercial scale the inventions he makes in his own laboratory; but this severe opposition is on the whole beneficial, and compels experimenters to pause before publishing their results.

That gentleman is the author of several standard works on Science and Hygiene, and is still engaged in original research. Beyond extending the list of "Sanitas" preparations and the "Bactericides," so well known to medical men by his name, he from time to time communicates papers of much scientific interest and value to the Society of Chemical Industry, and to other bodies of which he is a very distinguished member. It is just possible that we shall hear more of Sanitas before the present generation is much older, and possibly Mr. Kingzett's indefatigable energy and love of work may lead to his preparing some inodorous form. which can be added to milk and other delicate foods, which exposure to heat turns bad; and what a brilliant future would await it could it be washed over meat in hot weather, and while preserving it for some days longer, not give it the slightest *soup-con* of turpentine smell or flavour.

ASSALINI'S FORCEPS.

By G. Cadogan-Masterman, M.D.

Three months ago there was some correspondence in the pages of a contemporary on the relative excellencies of Assalini's and the ordinary forms of English midwifery forceps. The former instrument is of unique type, and possesses several distinct advantages, and yet it is less generally used, and, in fact, less generally known than any of its congeners. And there is one peculiarity connected with its habitual use I have noticed too often to be accidental, and which speaks volumes in its favour—the active development or exaggeration of what astronomers call the personal equation. We have all, I suppose, our favourite instruments; but whenever a man takes to Assalini's forceps, it is always with a warmer feeling of appreciation than so simple a piece of blacksmith's work would at first sight seem capable of evolving; and so he comes to regard it as not only the best for ordinary use, but as superior to all others, and capable of meeting every emergency. But this, I venture to submit, is a mistake. I am very partial to Assalini's invention, but I carry in my by-no-means-heavy bag a pair of Lever's long, and those very feeble, yet most useful extractors, Simpson's short, forceps, and for this reason—Assalini's are only of medium length, not long enough nor suited for application above the brim. To use them there one's hand, as well as the instrument, would have to be within the vagina. And then, when the patient is properly placed on, or rather one-fourth over, the bed, it is so easy to pass Lever's forceps, if we only first introduce the well-soaped left hand into the vagina, with the knuckles lying against the sacrum, the narrow and comparatively light blades taking up so little room. And again, as the reverse of this, when the fœtal head is lying on the perinæum, and we only want to save that from laceration, or to shorten by an hour or so a lingering natural labour, even Assalini's seem to demand too much preparation, too much show of instrumental interference for so simple a business. Then it is that Simpson's little instrument—which can be slipped unnoticed up one's sleeve, and passed without the cognizance of the patient, or even the nurse—comes in so usefully, with the minimum of fuss, and during the femininely exciting moment of the birth of the child can be taken off, wiped and returned to the bag unseen. This is a point trifling enough, and yet one we should not lightly disregard. Rightly or wrongly, most women have a horror of instruments, although I have met with many multipara who have begged for their use as soon as possible; and any instrument, or legerdemain—using this word in its primitive sense—which reduces this antipathy is surely worth consideration.

Now, from the simple form of the blades and shanks of Assalini's forceps, they can be passed with the least discomfort of and disturbance to the patient. She will be lying, of course, near to the edge of the bed, but not over it; then one and the other carefully warmed and oiled blade can be passed beneath, and with a scarcely perceptible lifting of the bed-clothes, locked and left in perfect security, untied, until the moment for their use has come. There is no crossing of handles, no reversal of external and internal positions, no fumbling or *looking* for the lock. When they are rightly applied, the bolt slips into the socket without an effort; and if it do not, we have the valuable intimation that they are not properly—that is, diametrically—placed, and one or the other must be gently moved until it occupies its right position. Then, with a folded napkin rolled round the shanks, what a firm, assured grasp one has! It is as if the fœtal head were itself within one's fingers, or solidly welded to the blades. At the time of passing the vulva, when carrying the head forwards and upwards in the last section of Carus's curve, the handleless character of the instrument enables it to be guided easily between the maternal thighs, the right knee being raised by the nurse, whilst the foot still rests on the bed, which ensures rotating the hip outwards with relaxation of the perinæum, and is the best precaution against laceration whilst the final manœuvre is being performed.

The instrument, being entirely of steel, can always be absolutely disinfected—as it ought to be—after every case, by placing it in a hot solution of caustic soda. I have used

this most effectual of all plans—for the alkali dissolves every form of septic matter—for many years with all my metallic instruments, and am surprised that it is so little known. The closest of spirals, the most slender of catheters, can be cleansed by it as perfectly as a knife blade.

Assalini's forceps are of essential service in the very operation they tend to make the most rare—craniotomy; for, as the blades can be unlocked without loosening their hold upon the cranium, we have, by keeping the perforator in the long axis of the shanks, an unerring guide to the vertex. The horrible scissors can be thrust boldly in without the slightest chance of injury to the mother so long as this direction is preserved. Then, the points of the perforator having been pushed down to the *foramen magnum*, rotated, the crucial cuts made, and withdrawn, the forceps are re-locked, and we have one of the best of crushers and extractors—far better than the clumsy craniotomy forceps—without a change of instruments. Assalini's are, under these circumstances, far more powerful than any of English pattern, for the obvious reason that the only limits to the approximation of the blades are the resistance of the fœtal cranium and the strength of the operator. With forceps having a central lock or pivot the contact of the handles is the limit of their crushing power, as can be tested in a moment by grasping one's own arm between, say, a pair of Barnes's, and then with Assalini's forceps. Now, when the cranium has been opened, it has lost its fluid internal support, and can be crushed like an egg-shell, and within the safeguard of the scalp. I have only had to perform this revolting operation three times amongst over a thousand deliveries, but as I felt the incised head collapsing under my hand, I was thankful to know that one peril at least was absent, the possibility of lacerating the vagina with some sharp fragment of bone brought away with an unexpected jerk by the treacherous slipping of the more generally used instrument. I once saw a case in which the bladder was laid open by a so-called accident of this nature. I need hardly say that the blades should be thrust in as far as possible when they are used for this purpose, and that with the apices well under the base of the shattered skull, they make the best of tractors.

There is a fertile source of error in casually estimating what is called the relative "power" of different forceps; one is so apt to think that length and weight are the measure of it. Long forceps, from their more imposing, or, as Tyler Smith says, "martial" appearance, are often called more powerful than the short variety. But this is from forgetting that, being a pair of levers of the first order, the effective crushing or holding force transmitted from the operator's hand is in inverse ratio to the length of the shanks and blades compared with that of the handles. Therefore, an instrument with long handles and short blades is the more powerful; but none of English model can carry more than 72 per cent., I have shewn,[1] of the hand-force exerted, it is assumed, in the centre of the handles to the middle of the blades. Smellie's *short* forceps do this, Hodge's do more, but the latter are of French pattern, and unsuited for use in any but the French obstetrical position, which, although theoretically the best, is opposed to our nicer feelings of professional delicacy.

Assalini's differ from all others in having the fulcrum not near the centre, but at the extremity; they resolve themselves, therefore, into a pair of levers of the third order; and as they are grasped by the shanks about midway between the joint and the centre of the blades their "power" there is approximately half of that exerted by the operator, or 20 per cent. more than can *cæteris paribus* be obtained with Barnes's. And, as the strongest grasp cannot bring the shanks into contact, their holding capability is limited solely by the strength of the user; they cannot slip if they have been properly applied, that is with the apices as low as the fœtal cheeks, and the harder one pulls the more tightly they hold; whilst directly the hand is relaxed the child's head is relieved from all pressure save that of the maternal organs, and yet the forceps remain safely *in situ*, and have never to be tied.

An important factor in the power of these instruments is the rigidity of the shanks; we may grasp the handles of the ordinary form until we force them into contact and fancy that we are compressing the fœtal head with equal might; but, if the shanks be weak, and especially if flattened in the same plane as the face of the handles, this may be quite illusive, we are bending them, not squeezing the head. In using the long forceps, that is within the uterus, this matters little, for, except in cases of absolute uterine inertia, the pressure our hand can exert is trifling compared with the enormous strain of the contracting organ itself. A pressure of 100 pounds, for instance, on the handles of Simpson's long forceps, would give but forty pounds—assuming the shanks to be rigid—distributed over nearly one-fourth of the area of the head, which is as nothing compared with the *centals* of compression of a healthy uterus. We have simply to pull in the right direction during the pains; the womb will take care to keep the blades in place. But when the head is without the *os* the conditions are reversed, the human vagina, unlike that of the mare or cow, has little muscular power, and there we need an instrument with the maximum of holding capabilities as well as affording a good grasp for traction, and Assalini's fulfils both conditions most satisfactorily.

But, it has been objected, why go to the expense and take the trouble to carry three instruments when one—a pair of good, long forceps—can do the work of them all? For the same reason that I have three blades in my pocket knife—I could trim my roses, or my nails, or even mend a pen (for to the confusion of compositors I still hold to the grey goose quill) with the larger, but not so conveniently. And as for the cost, when one must spend at least £100 on a decent *armamentarium* for country practice, what does that matter. When a fœtal head is impacted low down in the pelvis, or perhaps is lying on the perinæum, to have to bring a patient over the edge of the bed, to re-disinfect, warm and oil a huge pair of long forceps, to have to hold them almost at arm's length, to demand tape for tying them, is more than the occasion requires. And, above all, it is making a fuss, alarming the patient, and very possibly putting her to a good deal of unnecessary pain. It is like brandishing a two-handed sword to kill some puny enemy we could despatch with a stiletto. As for my long forceps, I might almost as well leave them at home; I find I have used them three times in eight years, but, then, once was with a patient five miles from my house. I use forceps in about twelve per cent. of my cases, sometimes from absolute necessity, but more frequently from pity to the mother—with their aid, and with no added suffering, we can do in a few minutes the work which Lucina labours so hard to perform in an hour or more, and especially when I am anxious as to the integrity of the perinæum.

THE DRINKING WATER OF COWS IN RELATION TO SUMMER DIARRHŒA.

By A. W. Martin,

medical officer of health, gordon.

So much has been written upon summer diarrhœa, and the subject worked out so exhaustively by others, that it would appear as if there is little more to be said upon the subject, or ony fresh light thrown upon the cause or causes of the disease. The mortality from summer diarrhœa is excessive; last year it numbered nearly 6,500 for the months of July, August, and September; for the whole twelve months the deaths exceeded 12,000. It is, however, with summer or epidemic diarrhœa that this article refers to, for there is little doubt that the disease termed diarrhœa, and returned as the cause of nearly 6,000 deaths during the other months of the year, is totally different and distinct in its cause from that particular variety known as epidemic or summer diarrhœa. The two chief points which particularly strike one in the etiology of the disease are its coincidence with the hot dry weather, and the prevalence and fatality of it in children under five years of age, the great bulk of the disease and deaths occurring amongst infants and young children for whom milk forms or should form the staple diet.

The fact that infants fed exclusively by the breast very rarely suffer or die from the disease, yet others of the same age brought up on cow's milk are the ones in which it proves most fatal would naturally lead us to the conclusion that the cause is traceable to the difference in their food, and not to the heated atmosphere to which both are subjected. My experience with condensed milk, in nearly all cases, corroborates the testimony of many others, that if used exclusively in the feeding of infants, it rarely gives rise to choleraic or summer diarrhœa, but cases frequently occur in which it would appear as though such were the case from the mother's or nurse's statement; but on closer examination there is generally elicited the fact that the condensed milk started the diarrhœa; its food was then changed to fresh cow's milk, with the result that very quickly the child "took a change for the worse." The form of the disease which is started by condensed milk and other artificial foods, is generally simple or irritative diarrhœa, and should it not cease in a day or two, a change of food is nearly always tried, and the change generally made is to cow's milk. The one form presents the characters of a local disease, simple irritating matter in the stomach and intestines, non-septic; the other gives the symptoms of the introduction of septic matter into the system, and producing general poisoning. In the treatment of summer diarrhœa, little good is done unless milk is prohibited and the child put upon water or barley water, and should the milk from the same source be again given, the disease invariably returns; in many cases where condensed milk or farinaceous food has been given too soon after the attack, the diarrhœa induced has then been of the simple or irritative type. The fatality of diarrhœa each year is always in proportion to the temperature, a hot summer having a high fatality, and a cold wet summer the reverse. The relation of the summer heat to the different forms of diarrhœa, from personal observation, appear to be that simple diarrhœa is induced or aggravated directly by the heat, whereas the choleraic or summer diarrhœa is brought about indirectly by the prolonged hot weather.

In an article in the *Illustrated Medical News* of June 8th, 1889, on the report of Dr. Ballard to the Local Government Board upon the causation of summer diarrhœa, the following occurs: "It is an established fact that a high atmospheric temperature conduces to a high diarrhœal mortality, and a low atmospheric temperature to a low diarrhœal mortality; but its influence is exerted indirectly, and is subsidiary. The temperature of the earth is a far more important condition, and Dr. Ballard has established that the summer rise of diarrhœal mortality does not commence until the mean earth temperature at a depth of four feet from the surface has attained somewhere about 56° F., no matter what may have been the temperature previously attained by the atmosphere, or recorded by the one-foot earth thermometer; and the maximum diarrhœa mortality of the year is usually observed in the week in which the temperature recorded by the four-foot earth thermometer attains its mean weekly maximum. Similarly the decline of the diarrhœa mortality coincides with the decline of the temperature recorded by the four-foot earth thermometer; but as the temperature at this depth declines very much more slowly than at the surface, so the epidemic mortality may extend somewhat into the fourth quarter of the year. Rainfall has probably only an indirect influence, and acts by affecting the temperature. Dry seasons and calmness of the air are favourable to the diarrhœa."

"Water pollution has little or nothing to do in the way of direct causation, but certain undefined polluted conditions of drinking water have from time to time appeared to give rise to epidemic diarrhœa."

"Dr. Ballard does not think the epidemic diarrhœa arises from indigestibility of food, but is due to some substance occasionally injected with food, and contaminating the latter. Infants fed upon the breast are remarkably exempt as compared with infants otherwise fed, especially those brought up with artificial food, to the exclusion of breast-milk, and exposed to neglect from one cause or another."

In those cases where the milk supply is suspected of being the cause of the diarrhœa, the contamination is supposed to have taken place between the time of leaving the cow and being taken into the stomach. In many cases such is probably the case, and as a rule giving rise to non-septic, simple, or irritative diarrhœa, but the type of the disease under discussion is the epidemic or choleraic form, and as the bulk of it appears to be traceable to the milk supply in children and adults, I propose to trace the cause to the drinking water of the cows rather than to the milk becoming contaminated after leaving them. It is well known that the milk of all animals is very materially affected by what they eat and drink. Up to the present, attention has been directed more to the effect of food upon the milk and its products than the water supply, yet it is obvious that the milk must be affected more or less by the water the cows drink also. The milk from cows fed on sour grains and on mangolds have repeatedly been proved to be the cause of diarrhœa. The milk of goats and other mammalia which have browsed on poisonous herbs has also proved poisonous. The water supply for cows in the majority of farms is dependent on the ponds, etc., in the fields, and it is easily seen how it becomes foul in the extreme after three or four weeks of hot weather without any fall of rain, from drinking, evaporation and their excrement falling into it; in fact, little or no difference to drinking warm sewage. The epidemic

of the summer diarrhœa commences "when the mean earth temperature at a depth of four feet from the surface has attained somewhere about 56° F., no matter what may have been the temperature previously attained by the atmosphere, or recorded by the one-foot earth thermometer; and the maximum diarrhœa mortality of the year is usually observed in the week in which the temperature recorded by the four-foot earth thermometer attains its mean weekly maximum." A heated atmosphere of some weeks duration, a ground heat of 56° F., or higher, at a depth of four feet, and the water saturated with excrement, forms suitable conditions for the development of micro-organisms, and the products of their life-processes.

It may be objected that if the water is so bad as to affect the milk it should also produce disease in the animal itself; but such is not necessarily the case. Many animals feed upon certain plants which render their flesh and milk poisonous, yet not deleterious to the animals themselves. "The poisonous nature of the flesh of animals which have fed on certain plants—for example, hares which have fed on certain species of rhododendron, pheasants on the calmia, etc.—has been abundantly demonstrated, and need only be referred to here. The honey from bees which have garnered on poisonous plants, as the azalea, may likewise be deleterious, and the fact is of classical interest. The milk even of goats and other mammalia which have browsed on poisonous herbs has also proved poisonous."[1] Our domestic animals—the cat and the dog—eat with impunity and relish such filthy putrid substances as no doubt would produce disease, in some form or other, with us.

"Milk may contain foreign bodies (in a changed or unchanged condition) which have been previously taken into the system."

The effects of food and drink upon the milk of a nursing woman is known to everyone. "The character of the milk depends to a great extent upon the feeding and exercise of the mother, and diet is the most important agent in regulating both the quality and the quantity of the milk. Many substances are excreted in the milk, such as ammonia and the aromatic oils. Amongst those which have actually been found to pass into the milk are the oils of anise, cummin, dill, wormwood, and garlic, as well as turpentine and copaiba. Volatile oils, having an agreeable taste, appear to render the milk more pleasant to children, so that they take the breast eagerly. Garlic, on the contrary, renders the milk disagreeable to children, so that they will not take it. Copaiba also renders the milk disagreeable. The administration of acids to nursing mothers is generally to be avoided, as they are apt to cause griping in the child. Neutral salts, as a rule, pass into the milk, and cause looseness of the bowels in the child. Senna, castor oil, rhubarb, scammony, sulphur, and probably jalap, act as purgatives to the child. Salts of potash, administered to the mother, will act as diuretics to the child. Turpentine, administered to the mother, also can be detected in the urine of the child, and this is also the case with copaiba and iodide of potassium."[2]

The distribution of the disease at the onset takes a course as if following the milk supply of certain farms, no doubt the milk becoming affected first at those farms at which the water supply is most deficient and contaminated. A wet cold summer determines a low mortality from choleraic, summer, or septic diarrhœa: the water supply is more abundant and less contaminated, and the grass being more abundant and succulent, the cows are not driven to the ponds by thirst so much as in hot weather; also the ground heat being less, the ponds are more filled with water and less contaminated, the conditions are less favourable for the development of micro-organisms.

"In Leicester, of 341 fatal cases, only two per cent. were suckled from the breast alone; the majority of them had some kind of artificial food; sixty per cent used cows' milk. As Cardiff has a very low prevalence of diarrhœa, Dr. Ballard asked the health officer how it was that diarrhœa was so slight, and especially amongst the Irish people. The reply was that the Irish of Cardiff got very little cows' milk, and the infants got no cows' milk."[3]

In the face of such evidence, it is not difficult to understand, from the drinking-water of the cow being charged with the chemical products of decomposition under the conditions mentioned before, how some of these chemical products may pass into the milk, either changed or unchanged; and, though apparently not affecting the animal itself, yet may be the chief cause in the production of summer diarrhœa in the human subject.

As all farms are not dependent upon ponds, etc., for their water supply, so all the milk sold in the heat of summer is not affected in such a way as to give septic or choleraic diarrhœa.

These few remarks and suggestions upon the causation of the disease may help to throw more light upon the milk theory, which apparently is so contradictory, and also coincides mainly with the deductions of Dr. Ballard in his provisional explanation of the malady.

"That the essential cause of diarrhœa resides ordinarily in the superficial layers of the earth, where it is intimately associated with the life processes of some micro-organism not yet detected, captured, or isolated.

"That the vital manifestations of such organism are dependent among other things, perhaps principally upon conditions of season and on the presence of dead organic matter which is its pabulum, that on occasion such micro-organism is capable of getting abroad from its primary habitat the earth, and having become air-borne, obtains opportunity for fastening on non-living organic material and of using such organic material both as nidus and as pabulum in undergoing various phases of its life history.

"That in food inside of as well as outside of the human body such micro-organism finds, especially at certain seasons, nidus and pabulum convenient for its development, multiplication, or evolution.

"That from food, as also from the contained organic matter of particular soils, such micro-organism can manufacture, by the chemical changes wrought therein through certain of its life processes, a substance which is a *virulent chemical poison;* and

"That this *chemical substance* is in the human body *the material cause of epidemic diarrhœa.*"

THERAPEUTICAL NOTES.

From our Berlin Correspondent.

Iodoform-Dermatitis and its Treatment—A new Salicylate of Soda—The Treatment of Burns—Hypodermic Injections of Mercury—A rival to Saccharin—The Treatment of Sycosis—The Physiological action of Adstringents.

Dr. Kolbe, of Rossleben, reports in the *Therapeutische Monatshefte* on *Iodoform-Dermatitis* He observed two cases of intense irritation and inflammation of the entire cutaneous tissue after external application of iodoform. In the first case a thumb had been amputated; the wound was dressed with corrosive sublimate gauze, and seemed to heal *prima intentione*. On the eighth day sutures and drainage-tube were removed; a very small quantity of iodoform was dispersed over the canal left after the removal of the drainage-tube, and the stump dressed with corrosive sublimate gauze and cotton wool. It was thought that further change of dressing would not be necessary. On the following day, however, intensive itching was felt all over the stump. On the third day this became quite unbearable; the dressing had to be removed, when it was found that the skin round the wound was red, œdematous, and covered with innumerable vesicles and blisters, containing serous fluid; some had suppurated and contained pus; others were already found emptied. The size varied between a hemp-seed and a hazel nut. This vesicular eruption implied the whole hand with all the fingers and the lower third of the forearm. It was treated with bandages moistened with one per cent. carbolic acid, under which treatment the dermatitis passed off in the course of a few days.

The second case of iodoform-dermatitis happened in an ulcerated leg which had existed for two years. One year ago the patient was advised to have some iodoform vaseline put on her ulcer. A vesicular eruption with signs of intense inflammation ensued. Kolbe not having been informed of the patient's peculiar idiosyncrasy towards iodoform, again applied it on the ulcer. After two or three days the whole leg began to appear red and swollen; intense itching and burning was complained of, and the skin soon became covered with blisters, which bursted, discharging great quantities of serous fluid. Some of the blisters were of much larger size than in the first case After application of

Acid carbol... ..... gr. x.
Ol. olivæ .....
Ol. terebinth .....āā ʒ ss.
f. linimentum.

the skin soon was restored to its normal appearance.

"*On Dithiosalicylate of Soda ii.*" is the title of an interesting communication made by Dr. Lindenborn, physician to the Municipal Hospital of Frankfort-on-the-Maine, in the *Berlin Klin. Wochenschrift*. Dithiosalicylate of soda i. and ii., as prepared by Baum, are two isomeric substances of the following chemical constitution:

$$\begin{array}{l} S{-}C_6H_3{<}\begin{array}{l}OH\\CO.\,OH\end{array} \\ | \\ S{-}C_6H_3{<}\begin{array}{l}CO.\,OH\\OH\end{array} \end{array}$$

They therefore contain two molecules of salicylic acid bound to two molecules of sulphur. The salt N ii., to which Lindenborn's experiments were confined, represents a greyish-white powder, very hygroscopic, entirely soluble in water. Any acid added to the solution produces a precipitate of yellow viscid drops, consisting of dithiosalicylic acid. Perchloride of iron added to the aqueous solution of the soda salt produces a faint violet colour. He administered the preparation to a patient for about eight days, and failed to discover salicylic or dithiosalicylic acid in the urine.

According to the researches of Hueppe a twenty per cent. solution of dithiosalicylate of soda is able to destroy the spors of anthrax in the course of forty-five minutes. Simple salicylate of soda submitted to the same test has no such action. Experiments with cholera and typhoid bacteria, staphylococcus aureus, and the microbes of the blue pus, furnished results equally favourable to dithiosalicylate, which, therefore, as a disinfectant and antiseptic is much superior to salicylate of soda. Up till now he used dithiosalicylate ii. in five cases of rheumatic fever, in four of which several joints were affected, in one only one joint was implied. He also used it in a case of gonorrhoic rheumatism, complicated with srido-chorioiditis. In the slighter cases he prescribed three grains to be taken twice a day, morning and evening; in the more serious cases three grains in the morning, and the same repeated two to four times in the evening, one hour's interval intervening between each dose. In the slighter cases fever, pains, and swelling of the joints entirely disappeared after two days; in the more serious after six days at the utmost. In one case recurrence was not prevented, but in this case a relapse had previously followed the salicylic acid treatment.

A reduction of the evening temperature, amounting to 2-3°, was produced by two to four doses of three grains each. A temperature of 102.4° was after three hours reduced to 100°; another of 100.4° to 98.4°, and 100° to 98.4°, etc. A decrease of the frequency of pulse in proportion to the abatement of temperature was constantly observed. Humming of the ears and nausea never occurred; sweating was confined to cases where upwards of twelve grains had been given in the course of one day.

One case of gonorrhoic inflammation of the knee-joint had at another hospital been treated with salicylate of soda, the daily dose amounting to 1-1½ drachms of this salt. At the Frankfort Hospital, where the patient subsequently was transferred to, this treatment was continued for twelve days, but to no avail. Pain and swelling of the knee did not disappear, and the evening temperature remained at 100° to 101°. It was now resolved to try dithiosalicylate, three grains twice a day. Soon after this treatment was began the evening temperature never went above 99.6°, and ten days afterwards the patient was entirely cured, and fit to go to work again. The antipyretic action of the drug was tried in a case of consumption; doses of six grains in this case had no effect whatever on the temperature.

Lindenborn claims the following advantages of dithiosalicylate over ordinary salicylate: It has a powerful action; it need not be given in such large doses as salicylate; it has no ill-effect on the stomach, nor on the heart or great vessels; it does not produce collapse, nor humming of the ears. The author states that further trials will, of course, be necessary with this new antirheumatic. It suffices for him to have drawn the attention of the profession to a preparation which may, he confidently hopes, be of avail

in the often long and tedious treatment of some rheumatic affections.

In the *Pharm. Post* the following *Treatment of Burns and Scalds* is recommended: The affected parts are first washed with an antiseptic lotion, boracic acid solution (1 in 30) being the best; they are then covered with antiseptic paper, which contains one per cent. of boracic acid, and which has been dipped into a five per cent. solution of cocaine. A layer of absorbent cotton-wool is placed over the paper, and the whole dressing is left for a few days. Pain is immediately relieved by this treatment; boracic acid secures antiseptic healing, which is effected in the course of a few days.

Soukhoff, in the *Pharmaceutische Zeitung*, recommends *Injections of Vermilion* instead of the mercury preparations usually employed for subcutaneous injections. He claims the following advantages for this new method: non-irritability, absence of pain, excellent effect. He used the following formula:

Cinnaboris ..... ʒ i.
Ol. Amygdalæ ..... ʒ i.

If his experience should be confirmed it would, perhaps, be even more advantageous to replace the red crystallized sulphide of mercury called vermilion by the black sulphide of mercury, which may be prepared as a much finer powder, and which formerly used to be an important constituent of the pharmacopœia of our forefathers under the name of Æthiops mineralis.

Methyl-benzoic Acid Sulphinide is the somewhat complicated name of the latest rival to saccharin. It is claimed for this new preparation that its sweetening powers considerably excel those of saccharin. A finest crystal needle of two mm. length, dissolved in a tumblerful of water, is said to taste as sweet as the sweetest syrup.

The most effective treatment of *Sycosis of the Beard* is said to consist of inunctions of iodoform lanoline. Alfred Loech, in the *Deutsche Med. Zeit.*, recommends the following formula:

Iodoform precipit..... ʒ i.
Lanoline ..... ʒ i.
f. ungt.

A small piece of this ointment is, every evening, rubbed into the affected parts, the beard having previously been washed with hot water.

Dr. Heinz, of the Pharmacological Department of the Breslau University, has made extensive researches on the *Physiological Action of Astringents*. The experiments, the results of which are published in *Virchow's Archiv.*, imply the following astringents: tannic acid, alum, acetate of lead, sulphate of zinc, perchloride of iron, sulphate of copper, nitrate of silver, and corrosive sublimate. The veins of cold-blooded animals were contracted by very weak solutions of these substances, the strengths being: corrosive sublimate 0.05 per cent.; nitrate of silver, acetate of lead, and sulphate of zinc, 0.1 per cent.; perchloride of iron, sulphate of copper, tannic acid, and alum, 0.5 per cent. In warm-blooded animals styptic effects were distinctly manifested by solutions of the following strength: sulphate of zinc, acetate of lead, tannic acid, five per cent; nitrate of silver, sulphate of copper, two per cent.; perchloride of iron, and corrosive sublimate, one per cent.

THE ASPIRATIONS OF AMERICAN MEDICINE.[1]

By W. W. Dawson, M.D. (Cincinnati).

The Premier, Mr. Gladstone, after quoting the statistician who estimates the English-speaking people at the close of the next century at one thousand millions, says: "What a prospect is that of many millions of people, certainly among the most manful and energetic in the world, occupying one great continent." This destiny in numbers is startling, but the assertion of Dr. Dollinger, a German scholar, portrays the culture of the future almost as strikingly when he says "that the intellectual primacy of the whole world is certain to fall to the Anglo-Saxon race." Most of that race will be in America.

Looking to such a future the position of the learned professions is certainly conspicuous—their obligations imperious. Medical men should be loyal to this grand destiny. An eminent modern critic, in discussing civilisation in America, while admitting that we have well solved the political and social problems, asks what have we done to solve the human problem, "the humanisation of man in society." The struggle in his own country, he asserts, has resulted in "an upper class materialised, a middle class vulgarised, a lower class brutalised." We trust that our efforts have yielded better fruit; and since medical science and medical men are prominent factors in society, among every people, we may well ask, what have they accomplished, what part they have here taken in the solution of the vital problem? In the "Century of Medicine," Prof. E. W. Clark in his classical address says: "It is not an extravagant assertion to say, that in all this turmoil, change and progress (referring to the revolutions and changes in society, religion and government for the past century), medicine has kept abreast of the other natural sciences, of politics, and of theology, and has made equal conquest over authority, error and tradition," and it may be added, has contributed largely to man's comfort, happiness, and advancement. To intensify this, reference need only be made to some of our triumphs, to vaccination, to anæsthesia, to sanitation, the prevention of pestilence, the lengthening of human life. It is, however, more especially the contributions of the profession in America to which attention is desired at this time. What are we doing in the humanisation of man, in the work of civilisation.

Are our medical practitioners and our medical teachers what they should be? We shall see. Criticisms abound concerning the defects of medical education. Those who do not condemn, often ridicule. These criticisms and strictures are made for the most part, it must be said, by gentlemen unacquainted with teaching, without any practical knowledge of the constitutions of medical colleges, or of the toil, devotion and sacrifice made necessary by those engaged in didactic and clinical instruction.

These censorious addresses are delivered before and to a body of professional gentlemen, the peers of any, some of whom have grown gray in the hard service, others are still in the prime of life, with reputations coextensive with civilisation. The rest are young, full of life and enthusiasm, fired with ambition to render loyal service to that profession which they have chosen. Can our system be so defective? The pessimistic orator seems to forget that he is the product

[1] Delivered at the Fortieth Annual Meeting of the American Medical Association, Newport, R. I., June 25th, 1889.

of the system of medical education which he is so severely condemning. Some one has said, "By retrospection and introspection and individual, like a profession, may be benefited." In this self-examination we should have but one motive, the elimination of error, the development and support. Education cannot make all great or equal. It tends, however, to make all safe. In the crucible of private, practical life, evolution asserts itself and the fittest survive. In making a retrospect of our profession it may be well to look for a moment at medical teaching in this country.

The way is long between Aristotle, and Bichat, and Buckle says that he found no middle-man in this long period; it is darker than it is long. During all this time medicine was not taught legitimately. The renaissance, if it may be so called, began with Hunter and Bichat. No real progress, however, could be made while oxygen remained locked in the silent embrace of all organic and inorganic nature. Priestly, escaping from the religious and political contests, and it may be persecutions, of the world, came to this country to demonstrate his great phlogiston, oxygen.

Bichat and Hunter restored the proper study of medicine. They represent the turning-point from idealism, speculation, and theory, to accurate and close observation. The latter, John Hunter, in 1767, was lecturing and taking students into his own house, and it is curious to know that here, in far off America, Shippen and his contemporaries in Philadelphia and New York, about the same time, or very soon after, began teaching medicine and surgery upon essentially the same plan. Of these men, one who so recently passed away, that you can almost hear the sound of his voice, and feel his magnetic presence, when speaking of the men who lived at the close of the last, and during the early part of this century, said, and justly said, "Not a few of them were the worthy peers of Roux, Abernethy, Crampton, Bell, Graefe, and Scarpa."

To quote again: "During the past century, medicine has been enfranchised from superstition, *quasi*-charlatanism, bold empiricism and speculation, and has developed into a symmetrical science, affiliated with other natural sciences, studied by the same methods and by the same appliances as they are, and like them, has been planted upon the solid basis of fact and demonstration." It may be profitable for use to inquire and determine what part the profession in America has taken in placing medicine upon the high ground which it occupies. What have we done, what are we doing, and what forecast can we make of the future?

At the close of the eighteenth century, Boerhaave declared that all that had been learned up to that time was comprised in three propositions: "Keep the head cool, the feet warm, the bowels open." All other pages in the volume which he left were blanks. Many pages, however, it will not be denied, have been filled during the present century. What have been our contributions? Have they been such as to rank us with the acknowledged conservators of mankind?

In giving attention to this subject let us for a moment reflect upon the peculiar position of the profession and of medical teaching in this country. For many years (and even now) with few exceptions, medical colleges were the creation of the members of the profession, most often of the faculties composing the schools, without endowment—indeed, it may be said that almost everything on this continent is endowed, except medical colleges—without Governmental aid, depending for their support upon the sacrifice of time and money on the part of the gentlemen occupying the chairs. Yes, not only without patronage from the Government, but society, from some unknown causes, has ever been against legitimate medicine, depending upon the scientific physician in time of trouble, yet, in the interim, openly supporting all sorts of shams, frauds, and impostors. Elsewhere, college work is provided for by the State; especially laboratory investigations—the nature and the genesis of disease. Hence, it is not strange that in such departments we may not be so far advanced as our European brethren; but, while we have engaged in experimental studies, we have developed the practical. But everywhere is seen among us an earnest, a burning desire for higher culture, for more exact and accurate knowledge. Especially is this true of our younger members and of those about entering the profession.

A movement is being made to cencentrate those who have had preliminary advantages—those who enter the profession as college-bred. No objection can be urged to this if it be not too exclusive. All efforts, in fact, to refine our profession without emasculating it, should meet with judicious approval.

THE PHYSICIAN OF THE FUTURE.

Whence are medical students to come? What facilities are now afforded, and what does the future promise for the education of our young men, the class from which the medical student, the "coming doctor," is to be selected? The answer to this question will give some comfort, we trust, to the pessimist, and soothe the restless and at times unreasonable critic. And now as to our resources for this work.

By the last census it was shown that nearly four thousand institutions—schools for higher learning—existed in the United States, and that nearly four hundred of them ranked as Colleges or Universities. In these are massed, yearly, sixty thousand pupils. They, together with two hundred thousand common, or primary schools, in the higher grades of which the curriculum nears that of many colleges at home and abroad, a third of a century ago, may be looked upon to supply, year after year, a better material from which medical students will be drafted.

Prof. Charles W. Eliot, in his beautiful and forcible Centennial response, enumerated our educational facilities more generously. He painted our future more hopefully when he spoke of 8,000,000 children in elementary schools, 250,000 in secondary schools, 60,000 in colleges, with 360,000 teachers to train and develop them.

Everyone travelling through the States—especially those of the West and South, and those situated in the far away mountains, and on the Pacific—must be impressed with the onward march of public instruction, the gradually increasing general intelligence, and the vast sums that are annually expended for the education of the people. Public school buildings, by their size, adaptation, and attractive surroundings, give an impression which the most sceptical must feel, a promise for the future which cannot be misread. From such as these scientific medicine must reap a share. Every teacher, every one connected with the examination of candidates for the medical degree, knows—and the knowledge is reassuring—that, year by year, the grade of the medical student is advancing, that the material out of which the practitioner is made is constantly growing better, becoming stronger; in other words, that the preliminary education of

our students is steadily becoming more broad and comprehensive. I gave utterance to this view a few years ago, in an address which I had the honour of delivering to the State Medical Society of Ohio. Time, I believe, has confirmed what I then said. This confirmation is seen in our graduates as they go forth to take up the line and battle of life. Are they not the equals of the graduates in other professions, in law and theology? As life advances, are they not the peers of any, in all the useful elements of true manhood? Are they not the citizens of best rounded characters, citizens most relied upon by their neighbours in foul as well as fair weather?

Again, in addition to facilities already referred to, the most generous provisions are being made, all over the land, for institutions which will be worthy to be called universities. From these, graduates will emerge worthy to rank by the side of those bearing the prized degrees from Oxford, Cambridge, Paris, Heidelberg, or Leipsic.

During the summer of 1888 I witnessed the beginning of a university in California which, in scope and equipment, will surpass probably any school upon the continent. Should Governor Stanford live to develop his conceptions, that far-off State will have an institution of which not only the Pacific Coast, but our entire country; yes, all civilisation, will feel justly proud. It may be so liberally endowed that it will command the best abilities of the world.

Of course, upon such an occasion as this it would hardly be expected that I should in detail refer to the many liberal donations and bequests which have been made, by generous citizens, for developing higher culture—a more comprehensive education. I will, however, be pardoned for referring to a few, and I may say, without being too enthusiastic, that the future is aglow with promise. The high-hearted examples which have been set will be followed by other favourites of fortune, and this country may surpass the world, not only in common schools, but in her institutions for broader and deeper education.

In looking at this promising future, may we not hope that, before another half century closes, students from the old world will flock to this to sit at the feet of the wisdom here installed? Is it too much to hope that, in the not-far-off future, the preliminary education of our students will be equal to that required in the best schools of the world?

Defective as has been much of the material, yet have we not produced some marked results? Our best are equal to the best anywhere; mediocrity always and everywhere finds its own. The poor in medicine, the weak brother, however much we may deplore him, however much we may train him, we have, like the poor, always with us. This is the lot of humanity in all lands, among all peoples, new or old. A word as to the physical qualities of "the coming doctor." Recently a distinguished foreign traveller, in speaking of our educational facilities and national peculiarities, said: "Students are much calmer than their colleagues in Europe. They don't at all trouble themselves about politics or affairs outside their line of duty, and with the practical sense which animates the nation, they try to make the best use of their time. They fight no duels, and it is only for health and recreation that they take part in various sports and games." The remarks apply with equal, in fact, with greater force, to medical students.

It is to the country schools, not to the city-bred, that medicine must look for many of her strong recruits. Cities too often emasculate—young men are vitiated by indulgence and vice before they become possessed of serious thoughts, before they realise the elements of a healthy, vigorous life. It is this country-bred, this excellent material which is, as we have seen, yearly growing better and better qualified to enter upon the duties of the profession. From these we must look for the men of distinction, the leaders of the future.

Is this picture overdrawn? One word more. In many of the States of the Union, in addition to the liberally supported free schools and schools for higher education, already colleges have been established through the munificence of the General Government, in which the degrees of A.B. and A.M. may be obtained. They are absolutely free colleges, at which the poorest boy in the commonwealth may receive a classical education. And here you will allow me to say, we cannot insist too strongly upon the necessity of classical education; without it the medical man must ever be at a disadvantage. Without a knowledge of Latin and Greek sure and distinguished success is uncertain. The student may neglect algebra and the higher mathematics, but let him by all means have a liberal knowledge of languages.

At the last commencement of one of our western schools "forty per cent. of the graduating class had been admitted on diplomas from literary or scientific colleges. The balance of the class had received from one to five years of academic or collegiate instruction." This college is without endowment—depending entirely upon the learning, devotion, and sacrifice of the faculty.

But to return. Prominent among the States in providing institutions for advanced culture, the great frontier state, Texas, claims a high position. The University of Texas will be one of the most liberally endowed; millions of acres of land have been donated for university purposes. There, in that Empire state, may yet be seen one of the greatest schools of literature, science, and philosophy on the Western Continent. The university of Virginia, projected in the early days of the century by her great commoner, Thomas Jefferson, has yearly sent forth graduates equal in all the elements of advanced scholarship to those from any school.

This may seem high praise, but the records of her alumni justify me. The same may be said of Harvard, Yale, Princeton, Columbia, Cornell, and of most of our older institutions. The University of California has already an annual revenue of about $200,000. The Michigan University, with a yearly income of almost a quarter of a million of dollars, has well nigh two thousand students, taught by more than one hundred teachers.

Let us not, gentlemen, be impatient. The influences are already projected which will give us students equal to—up to—the highest standard of preliminary preparation. If we have accomplished so much in our primitive stage, what may we not expect when all our great preparatory works come fully into action?

From this view of the resources from which medical students are to be drawn, and of the liberal preparations and facilities for their culture, we may well ask What is the profession doing to profit from such advantages?

Some of the classical schools at Oxford and Cambridge were organized as early as the thirteenth century, but the systematic, scientific study of medicine and surgery came long subsequently—not for four hundred years later—about the middle of the eighteenth century. It was first projected

in Great Britain, and soon after in our Atlantic cities. Unlike the Old World, our fathers had a wilderness to conquer before progress could be made. When the pilgrim fathers left England, reading and writing were rare accomplishments; chimneys in that country had just been invented, and flock beds were luxuries. The adventurers—the emigrants to these shores from that ancient and imperfect civilisation—had much to learn, but in the midst of their pitiable ignorance, facing great hardness and pressing wants, they were quick to provide educational opportunities for all. The results of their efforts are apparent—they are before us. Could more have been accomplished in one century?

MEDICAL SCHOOLS.

Our medical colleges now number a few more than one hundred. They may be classed as: 1. Metropolitan, those in large cities. 2. Medical colleges in less pretentious cities. 3. Medical colleges in small cities. 4. State medical colleges. For convenience, however, we may speak of them as metropolitan and provincial.

Before speaking more definitely of our medical institutions, allow me to refer for a moment to the proposition, that medical schools in our country have been developed by the labours, by the self-sacrifice of the profession. As previously stated, it may be said that in this country everything is endowed except medical colleges, schools for teaching medicine. Yes, all financial responsibilities have been and are assumed by the faculties, by men who give every hour not devoted to "earning the guinea" to college work, and in most instances with pecuniary reward. It is only recently that the wise, the generous, the favourites of fortune, and a few of the States, have conceived the idea of endowing medical schools, institutions where medicine and surgery can be cultivated without the embarrassments of financial responsibility. In the presence of such facts the work of the grumbler seems, indeed, ungracious.

In our metropolitan colleges, every physician may feel a just pride. Their graduates, most of them, will compare favourably with those educated anywhere on this earth.

The accomplished Dr. Senn, after a liberal experience with foreign schools, said: "There is no question in my mind that the average American student learns more in one month than the average German student in three. He learns more, not because he has better teachers or better facilities, but he makes better use of his time. I am satisfied that in our last graduating class I had at least a dozen students, who, after studying three years, would pass a brilliant examination in any English or German university. They would have felt at home, even in a dress coat in Volkmann's Klinick, passing their final examination."

Provincial schools do praiseworthy, yes, thorough work in training young men, not only in rudimentary branches, but in practical, clinical studies. Many supplement these by hospital attendance in the great cities, and by post-graduate courses. It is gratifying to know that these organizations are being established in all of the great medical centres.

The advance in medical education is again most distinctly pronounced by a remark recently made by one of our distinguished fellows, an American-bred physician, of whose fame we are all justly proud. In a conversation, Dr. Batty said: "When I began the practice thirty years ago, there was scarcely a graduate within fifty miles of my residence; now, however, there is hardly a practitioner in the same territory who is not a graduate, and, year after year, a portion of our young men leave home to avail themselves of clinical advantages, to attend post-graduate instruction." Could anyone show more forcibly the conservative and steady growth of medical culture.

HAVE MEDICAL COLLEGES INCREASED TOO RAPIDLY?

Should they be established in small cities where clinical material is limited, where it must be comparatively scarce? Before answering this, it may be well to reflect upon the proposition, that in our own country, as well as elsewhere, great achievements have often been made in the Provinces and not always under the shadow of the Universities. One of the great operations waited for years for a metropolitan disciple—one to take it up—and that too, long after the provinces, at home and abroad, had demonstrated its vital utility, its claim upon the scientific and skilful surgeon.

As our population increased from three to sixty-five millions, the demands for medical men were great—colleges increased necessarily. Have they multiplied in undue proportion?

In answering this question, I beg again to quote from my beloved master, Samuel D. Gross, to whom this question had been put. After mature deliberation, he said: "Our colleges are not annually graduating one physician for each county in the States and Territories. This is certainly not exceeding the demand." A considerable proportion of those who graduate never enter the ranks—death and desertion claim a large share. It would simply be impossible for the metropolitan schools to graduate all required.

For the introduction of young gentlemen into the profession, there is mutual responsibility between teachers and preceptors. In very truth it may be said that colleges do their duty, their very best, with the students furnished by the preceptors. Give us liberally-educated young gentlemen, and we will furnish graduates worthy of the degree. Medical colleges, however, do not make the physician; they merely furnish the foundation work; the individual must do the balance. In no place is evolution so marked—the fittest will and should survive.

LABORATORY WORK.

Huxley says:—"The microscope extends the realm of pathological anatomy to the limits of the invisible world." "The intimate alliance between morphology and medicine has made the natural history of disease attain a remarkable degree of perfection."

Dr. George M. Sternberg, the distinguished pathologist, recently connected with the Smithsonian Institution, in referring to some of the laboratories established in this country for the study of pathogenic micro-organisms, says:—"It is no longer necessary to go abroad for instruction in this department of science since the laboratory of Professor Welsh, in Baltimore, and the Hoagland Laboratory, in Brooklyn, afford facilities which are unsurpassed by any of the laboratories of the old world."

Indeed, it may be said that provisions for the study of pathogenic micro-organisms are established in most of the leading schools of this country—in New York, Philadelphia, Boston, Baltimore, and the cities of the West and South. You will pardon me for mentioning some of the investigators. John Hopkins' University has for its Director, Prof. William Welsh. The Hoagland Laboratory, of Brooklyn, New York, established through the generosity of Dr. C. N. Hoagland, has been built and equipped in the most complete

manner for research work in bacteriology and experimental pathology. Prof. George M. Sternberg is to be the director of this advanced institution.

At the University of South Carolina, Dr. Meade Bolton, who has had the best of training at Berlin and Göttingen, is at the head of a laboratory. Dr. H. C. Ernest has the direction of a bacteriological laboratory in connection with the Harvard School of Medicine. Prof. James T. Whitaker, who had the honour of being the first American student of Robert Koch, demonstrated, at Cincinnati, in 1882, the tubercle bacillus, after a lecture upon the subject before the Philadelphia Academy of Medicine. In 1887 the Medical College of Ohio imported a complete outfit for bacteriologic study. The conductors of the laboratory, Drs. Rachford, Cameron and Freeman, during the first course, had the opportunity of doing some good work in the discovery of the typhoid bacilli in the reservoir supplied from the Ohio river, then at a very low stage. The discovery led to the general adoption in the city, as advised by leading physicians, of boiling all drinking water, a plan which undoubtedly limited the spread of the disease.

Among others may be mentioned Dr. Prudden, of the College of Physicians and Surgeons, of New York; Dr. Geo. A. Kemp, of Brooklyn; Dr. Mall, of Baltimore; Dr. Booker of the same city; and Dr. Frank S. Billings, of Lincoln, Nebraska. One of the earliest, most accomplished and accurate cultivators of micro-organisms, is Dr. James E. Reeves, of Chattanooga. His technique is singularly beautiful. Many of his preparations are to be found in the National Museum.

Dr. Victor C. Vaughan and Dr. Heneage Gibbs, conduct laboratory work at Ann Arbor. The University of Pennsylvania has at the head of its laboratory Dr. John Guiteras, a Pathologist who has distinguished himself in the study of the origin and spread of yellow fever.

Thus it will be seen that in all parts of our country—East, West, North, and South—laboratories are being established for original work.

HISTORY OF MEDICAL TEACHING IN THIS COUNTRY.

A brief review of medical teaching in this country will be pardoned—it may be profitable—it will certainly illume the present, and may be somewhat of interest to the future.

The first medical lectures were delivered by Dr. John Morgan and William Shippen, in 1767, in Philadelphia. Dr. Rush and Dr. Physic soon after participated, and in 1768 the medical department of the University of Pennsylvania was organised; that great school which is steadily advancing to the highest station. Philadelphia was a small, provincial city at that time; now she is only second to the great metropolis in numerical strength, but second to none in the thorough equipment of her medical schools.

Contemporaneous with Philadelphia, an organisation was projected for medical instruction in New York. In 1767, the first steps were taken which resulted in the school ever since known as the "College of Physicians and Surgeons," one which challenges the confidence of all. The medical colleges of New York, endowed, not by government, but by her public spirited citizens, have won the honours which they wear so well.

In 1785, the first school was organised in Boston. The chairs were four, and the session four months. Harvard is the outgrowth of this humble beginning of that provincial faculty. In 1800, the first medical instruction was given in Baltimore; since then, the schools of Maryland have occupied a deservedly high position. Recently one of her citizens made an endowment by which the "John Hopkins University" will be equipped for the most thorough work, experimental work, laboratory studies, a range and grade of investigations *en report* with the spirit of the times. This great benefactor has also given to Baltimore one of the most completely equipped hospitals to be found on this earth.

The great Mississippi Valley was yet unknown, but soon after the close of the Revolution, emigration began, and as early as 1799, Dr. Samuel Brown organised the medical department of Transylvania University. Dr. Benjamin Dudley effected a reorganisation in 1819. This school, after many prosperous years, having graduated men who acquired distinction at home and abroad was transferred, or rather, most of the faculty removed to Louisville, when and where the University of Louisville was founded.

During the early part of the century, medical schools were organised in several of the Eastern States, usually under State or Church patronage. Most of them exist to-day. Some of the most distinguished men in our profession have been associated with these institutions.

As the West and South were peopled, medical schools were established in cities and promising towns. As early as 1819, Dr. Daniel Drake secured the charter of the Medical College of Ohio, and it was legally connected with the City Hospital. The faculty constituted the hospital staff, the members of which were required to give clinical lectures—the first forward step on the continent, in blending didactic with clinical instruction. The physicians in South Carolina began medical teaching in 1823, and those of Louisiana in 1835. In both of these states schools of high character have been maintained.

In closing this very brief review of our colleges, metropolitan and provincial, I think it may be said that year after year the standard of the doctorate is being elevated, preliminary examinations and graded courses are being adopted; the smaller schools, to which blame is most attached, whether justly or not, with a disregard of self-interest seldom seen, are yearly reducing the size of their classes by insisting upon higher preliminary education, by extending the curriculum, and by graded instruction.

MEDICAL JOURNALS.

Medical journals, metropolitan and provincial, are the heralds, the vanguards of medical progress, the exponents of professional culture. They are closely associated with the colleges in education, and in post graduate instruction. In them appear the best thoughts of the best men; they constitute the great forum of intellectual combat; upon pages pretension is analysed and estimated, and worth recognised; that which is new or original is endorsed, or rather encouraged; it is only the plan, the original investigation which is endorsed; the results, the conclusion must be subject to the crucible of test and trial.

The London *Lancet* and the *American Journal of the Medical Sciences* were almost contemporaries—who can over-estimate their value—their influence in medical progress. While our journals, both metropolitan and provincial, are freighted with the best thoughts of the best men, yet, it must be confessed, that trash and light material—very light material—may be found in all, but the reader, nevertheless,

will find much that is not worthless. The *Journal* of this association has won its way to its present high position by its dignified course and its essentially scientific character; but has it reached its full usefulness? A learned and distinguished author, and a highly prized fellow of our association, at my suggestion, gives his views upon this question. Dr. Comegys says: "The undertaking, seven years ago, to establish a weekly journal, was a happy conception, and has been carried on as successfully as the resources of the Association would admit. To Dr. N. S. Davis unstinted praise is due; proportionate praise is also due to the Board of Directors with whom he has been associated.

"A large number of the members believe that it is entirely feasible to enlarge the journal, and give to it increased capacity for usefulness; indeed, that it should be made more fully capable, as the organ of the Association, to assert and maintain the dignity and power of the medical profession as one of the greatest factors in civil life; that to it society must ultimately turn, to find, not only the resource to assuage the distress arising from the diseases and accidents of life, but as to its protection from all those evils that fill the land with apprehension of desolation and ruin.

"We know to what an immense extent we can stop the approach of the pestilences that desolate lands and which menace, through the paths of commerce, the whole area of civilisation. We know what we can do to improve the homes and places of labour of the lower and toiling classes of cities and other crowded centres of population. There is nothing, indeed, connected with our own social State, which the medical profession should not supervise and which it should not have the power to control. A great organ is necessary to enlighten, strengthen, and lead the profession in all directions to bring to bear its beneficent agency for the correction of the terrible evils of society.

"Such a journal must be made encyclopædic in character, in which can be found the proceedings of distinguished societies of this country and of Europe, the work of the chief actors of medical progress in all parts of the world. Twelve thousand subscribers would give $60,000, this would insure $40,000 from advertisements, making an income of $100,000, which would sustain one of the grandest journals in the world.

The *British Medical Journal* in fifty years has 14,000 subscribers, and an income of $125,000. May we not hope to reach this, and when we do, who can compass the good which the American Medical Association will accomplish?"

THE MEDICAL AND SURGICAL LIBRARY AND MUSEUM AT WASHINGTON.

Another important factor in professional culture is the great Library and Museum at Washington, evoked by the efforts of an American bred physician, John S. Billings. The Library of the Surgeon-General's office of the army now contains 92,000 volumes, and 137,000 pamphlets, being the largest collection of medical literature in the world, and it is not only the largest, but the most useful. This is because it has an index catalogue, which not only shows what the library has of the works of any author, but for any given subject, indicates all the original articles in journals and transactions, as well as the books and pamphlets which relate to it, and thus forms a medical bibliography which saves an enormous amount of time and labour to those engaged in medical literary research. This catalogue is being published at the rate of one volume a year; nine volumes have been issued, and six more will complete the work. The Army Medical Museum is a great pathological school, and now contains over 15,000 specimens, being one of the eight largest museums in the world, and richer than any other in illustrations of military medicine and surgery. This library and museum are national in scope and character. They have, at least, been securely placed in a fire-proof building well adapted to their needs, thanks to the efforts of the medical profession, and we should see to it that they are maintained and increased to the highest degree of completeness and efficiency.

The medical profession asks very little of the General Government, but it does ask that these two institutions shall be made as useful as possible. The number of copies of the index catalogue which Congress authorises to be published is hardly sufficient to meet the demand, and the repeated requests for authority to publish an illustrated catalogue of the museum for distribution to the profession have not yet received any attention from Congress, and it is time we took the matter in hand. When we, who are the family physicians of our senators and members, say to them that is a thing that ought to be done and must be done, it is pretty certain that it will be done. There is nothing that will do more to promote higher medical education, to stimulate research, and to crown American medicine with honour, than to give ample means to this great library and museum to obtain materials and to publish widely the results.

MEDICAL AND SURGICAL HISTORY OF THE WAR.

This matchless record of military medicine and surgery is a marked testimony to the profession of our land. Let us for a moment compare it with similar work elsewhere. After the great Crimean war was over, its experiences collected, weighed, and analysed, how strange in the light of present surgery, and in what contrast with the lessons taught in our great conflict, is the record of McLeod upon one vital operation—trephining for fractures of the skull. In his "Notes on the Surgery of the Crimean War," that distinguished gentleman says:

"If any patients were lost from not having been operated upon, I never saw any of them, but I do know of some patients who died because they were subjected to operation."

And what a fearful commentary upon military surgery of that campaign McLeod makes when he writes:

"Thus it would seem as if severe fatigue, irregular, and, it might be, intemperate diet, are less injurious to men with fracture of the skull than the probings, pickings, and trephinings which form the more orthodox and approved practice."

It may be truly said that the judicious use of trephine during the conflict between the States, supplemented after the war by American surgeons, especially by one of our fellows, Prof. W. T. Briggs, led up, led surely, safely and steadily, to the achievements of Victor Horsely, the master of us all in brain surgery.

MEDICAL SOCIETIES.

Our medical societies, local and national, are great factors in professional progress. Not alone are they valuable for their social opportunities, but in and through them a vast amount of valuable matter is presented.

MEDICAL LITERATURE.

Had Sidney Smith been a physician and given to reading, he would not, even in 1850, have asked the questions: "Who reads an American book?" "What does the world owe to American physicians and surgeons?"

This reverend gentleman, this famous critic, could not have heard of Ephraim McDowell, whose brief paper, detailing his first three cases of ovariotomy, published in "The Philadelphia Repertory," in 1817, was of more value, did more for the conservation of human life than a score of ordinary publications. Our first half-century may be poor in books, but it abounded in strong, brave, conscientious and devoted men, men who, with the most limited resources, accomplished the grandest results. They compelled success because they deserved it. The ink was hardly dry upon that cynical pen when anæsthesia was presented by the profession so poor, as he supposed, in valuable works.

But what country or age can match, in great contributions to the relief of the suffering, McDowell, Sims, Bigelow, Sayre, Batty, and Emmett, and that trinity of men—Wells, Morton, and Jackson—who gave anæsthesia to the world. Think of anæsthesia and of its influence upon the progress of medicine and surgery. But yesterday a writer in the London *Lancet* gave a graphic history of its reception in London; how the great Liston, having a patient who could not nerve himself up to the point of consenting to have a limb amputated for strumous disease of the knee-joint, decided that, "if the insensibility could be insured and maintained for one minute, he would amputate.,' Reflect for a moment on the hesitancy of the great surgeon of University College Hospital, as he stood by the side of that patient; he could hardly believe the novel report as it came over the sea. Willing and anxious as he was to operate, he hesitated to urge the poor patient to make the experiment—experiment it then was. In a week, however, it was legitimate practice all over the world.

The heart of every American physician is filled with thankfulness when he remembers that in the Providence of God this great boon to humanity was vouchsafed to his country. The very ground upon which stands Massachusetts Hospital is sacred to us all. Associated with the discoverers must ever be the name of Dr. Hayward, who performed the first operation under the strange letheon. Previous to this, operative surgery was slow, tedious, and almost cruel. Contrast it to-day with what it was previous to 1847. What grand strides it has made under the direct support of anæsthesia and its almost equal co-labourer, antisepsis; the great cavities are invaded, and invaded safely; the abdomen has become a familiar field; and who can forecast the surgery of the brain?

Since Emmett's operation we hear no more, neither in this country nor abroad—neither in London nor Berlin, neither in Paris nor Vienna—of that culmination, that *ultima thule* of ignorance, "ulceration of the os." What a disgrace that term was to the surgery of the world! The ignorance in diagnosis was only surpassed by the cruel treatment which it evoked, the application of caustics to the tender everted membrane of the cervical canal.

Has the operation, Bigelow's litholapaxy, the crushing and evacuation of a stone at one sitting, been truly estimated? Its adoption in one celebrated case might have changed the destinies of Europe. Previous to Bigelow, lithotrity was an uncertain, and in most hands, a cruel operation—"Crush all possible at a short sitting, and allow the fragments to pass *via naturalis*." Bigelow realised that if anæsthesia is safe for two minutes, it is safe for two hours or more; hence, he said, "Crush it at once, and evacuate the bladder by an aspirator." The operation, in proper cases, is as practical as the description is brief and efficient.

The accomplished Edmund Owen, M.B., F.R.C.S., upon calculus, says: "With rare exceptions only two operations are now practised—suprapubic lithotomy and crushing, with evacuation at a single sitting." A high compliment from an eminent authority.

The story of Ephraim McDowell, though so often repeated, humanity never tires of hearing. To us he belongs, and to us only; we cannot share his fame with another; we would not if we could. Who can measure the relief which his operation has bestowed upon suffering woman? Not only woman, for his was the genius which opened the way for laparotomy in both sexes.

CLOUDS.

What has been accomplished by the profession in this country, self-reliant, and as we have heretofore said, without governmental or social support, is certainly worthy of congratulation, and gives ground for hopes of a rosy-hued future; but, alas! there are some dark clouds to be seen—some spots on our sun of promise! Have we inherent defects in our organic law—our *esprit de corps?*

Upon the face of our promising future some omens of evil appear, indications which look not up but down, not forward but backward, not to the elevation but rather to the degradation of our profession. Heretofore we were an organisation into which no species of fraud could enter; pretension, ignorant pretension, stopped at the door. No *ism* or *pathy* was admitted; something more than a diploma, "a legal diploma," was required—a clean bill of conduct, free from false assumption, assumption of universal knowledge, of specific remedies, of imaginary potencies; in fact, of all shams and false claims, a guild in which there was the greatest freedom for the truth, the largest liberty for the right. No vendor of secret remedies was admitted, because of the ignorant presumption in which they were conceived and propagated; but, alas, that we should have fallen upon the evil times when "patented processes" are attempted, when "processes" of valuable remedies are kept secret. These remedies with "patent processes" are in daily use. This is one of the dark spots in the picture. It came in with the "legally qualified practitioner." What is antipyrin, antifebrin, salol, sulfonal? The reliant patient may well propound such questions. Who can answer them? Are we relegated at one fell move back into outer darkness, the associates of vendors of "secret remedies," of patented processes?" What higher is a "patented processes" than a "patented nostrum?" The profession was never so low as to countenance the latter; but have we not, in these latter days, become propagandists of patented and, therefore, secret processes?

LAWS FOR THE REGULATION OF THE PRACTICE OF MEDICINE.

It may be asked, has the standard of professional excellence been raised by laws enacted in many of the States for the regulation of the practice of medicine?

These laws banish the poor creatures without diplomas, but make respectable, *quasi*-respectable, all who have so-called diplomas from whatever source. Shams and pre-

tenders are in this way "legally," and claim whatever protection and recognition that term may give or imply. A chartered institution, in most of the States, represents a formal application for incorporation to a Secretary of State, the signature of that officer, and nothing more. The process of graduating from such—the faculty often consisting of but a single person, or a man and his wife—would hardly be called a farce; the subject is too serious. "Legally qualified!" think of it; and yet this legally qualified creature will claim and expect to meet the highest and the purest. Is this an advance upon the requirements of the Code, the morals and *esprite de corps* of which have never been questioned? What has been the effect of these diplomas? Let any candid man answer. Have they not tended to make vice and presumptuous ignorance respectable? Let us be true to ourselves; pitch cannot be touched without defilement. Our profession must be kept pure or else it will degenerate and sink to the level of a trade.

In State Boards of Health, by the side of physicians, we find these "legally qualified" practitioners. Where lies the responsibility? It is with us? Our self-examination on this subject should be searching. If we have failed in our duties to humanity, let us be swift to acknowledge it, and be still more eager to correct our error.

The presence of this body of professional gentlemen, representing our entire country, furnishes sufficient argument for the existence of a national organisation, one embracing the virtue and strength of the profession, one to which all questions should be referred for just and final decision. Questions will arise, differences of opinion will occur between honest men. We must have some tribunal, some body, to which these questions, these differences of opinion, can be relegated for solution. The golden rule is a principle, not a law; it cannot interpret itself. Its application to life in detail must be defined. In this respect we are like other men and other organisations. Our *morale*, however, is higher; it has a zeal, a spirit, a hope and confidence peculiarly our own. If we would have our organisation pure, we should make it strong—strong enough to eliminate all that is not true or truthful. We are mortals, not transcendentalists. We cannot live as the commune. We must have law; remembering always that they are not made for the righteous, but for the sinner. "They that be whole need not a physician, but they that are sick." I will not attempt to defend the ethics of our profession. It would be a poor compliment to your intelllgence, to your manhood; for there is not a clause in our Code which a gentleman could not cheerfully obey. Organise whatever we may please: associations of specialists, of physicians, of surgeon; academies of physicians; congresses of physicians and surgeon; but let us not lose our loyalty to this parent association. Projected almost half a century ago, when medical societies were few, it has annually convened—in the north, in the south, in the east, and in the far west, on the Pacific shore. If you will examine its yearly roster, you will find that it embraced the best and the wisest. Almost all who were present at the beginning are at rest; their places have been filled by worthy men. Thus yearly new life—new men being added—this Association cannot grow old.

"When a people hold their lives and property as nothing, the enemy has already suffered defeat." So too, when virtue will not compromise with vice, the victory, although it may be long delayed, will surely come. Of the American Medical Association, let us unite in saying, *esto perpetua.*

Reviews.

The Diseases of Children, Medical and Surgical. By Henry Ashby, M.D. Lond., M.R.C.P., Physician to the General Hospital for Sick Children, Manchester, etc.; and G. A. Wright, B.A., M.B. Oxon., F.R.C.S. Eng., Assistant-Surgeon to the Manchester Royal Infirmary, and Surgeon to the Children's Hospital. London: Longmans, Green and Co. 1889.

This convenient octavo volume of 681 pages, well illustrated, and with a very complete index, deserves early notice, as supplying in a very complete manner the want long felt of a comprehensive treatise on the diseases of childhood that should bring together the various morbid conditions peculiar to or chiefly found in infants and children, written from a practical point of view, with a fair exposition of modern pathology. The scope and object of the book is set forth jointly by the authors in a short preface, as based on an experience of nearly ten years at the General Hospital for Sick Children, Manchester, where some 1,200 in-patients and some 10,000 out-patients are annually treated, and that during the whole time material has been collected, both at the Children's Hospital and at the Royal Infirmary, for the purpose in hand. The original feature of the book is that it is written conjointly by a physician and a surgeon. It will be useful, we think, to more than senior students and junior medical practitioners, "and it is at least based on experience, and is not a mere compilation." Full acknowledgment is given for the aid received in the course of the undertaking, and last, but not least, to Messrs. Longmans. The work is highly creditable to the Manchester medical school, and no doubt will in every way be advantageous to authors and publishers.

The work is divided into thirty-nine chapters, of which the first three are very advisedly devoted to the physiology and hygiene of infancy, with one on the accidents of birth. Diseases of the digestive system occupy seven chapters, one of these dealing with malformations. The respiratory organs claim three chapters, in which questions of tracheotomy and paracentesis thoracis, presumably from the surgical pen, are so much parts of the medical subject as to seem integral parts of treatment. Two chapters on the specific fevers, and two on the diseases of the circulatory system, are, except the last on nævi, chiefly medical. There are three chapters on general diseases, in which both authors are concerned. The five chapters on diseases of the nervous system are among the most interesting, with the latest information on the great advances recently made in this direction. The importance of early surgical interference in preventing the deformities likely to follow upon infantile paralysis is well illustrated. A section on surgical treatment of cerebral lesions affords another instance of how aptly the combination of surgical with medical details comes in. After two chapters on diseases of the genito-urinary system, where both authors are represented, come ten chapters chiefly surgical, but admitting of much medical comment in the diseases of the joints and spine where specific general diseases are concerned. One chapter of nearly twenty pages deals with diseases of the skin. There is also a chapter on injuries, one on anæsthetics, and an appendix dealing with the preparation of articles useful in nursing, and giving some valuable remarks on therapeutical agents.

Numerous well-executed illustrations are judiciously placed throughout the book, chiefly, of course, in the surgical chapters, but there are some dozen of a mixed character, and eighteen temperature charts in the more strictly medical part of the work. The large experience of Dr. Ashby in the management of the common infectious fevers, and his well-known accuracy of observation induces one to turn first to the specific fevers (pp. 211-269), where it is satisfactory to find so much of what is interesting, and almost all it is important to know of these popular plagues, brought within so compact a compass. A preliminary page on fever in children is perhaps too concise, as where small-pox and typhus are put with measles and typhoid, among diseases in which the temperature is gradually raised, "taking several days to reach its greatest elevation;" yet it introduces a caution applicable to all that "a diagnosis cannot be made for a few days till characteristic symptoms develop." We are here reminded of the sudden form of otitis, pneumonia, sunstroke, and some forms of diarrhœa; also of how convulsions in infants frequently take the place of the severe pain or delirium that mark the ingress of fever in older children, and to be on our guard in diagnosing cerebral disease when high temperature of the blood or a specific poison may cause cerebral symptoms, the brain itself being normal. The incubation period of each of the specific fevers, and the duration of infection after the diseases appear, receives special notice in the section appropriated to each. The short incubation of scarlet fever and its long period of infectiveness is very clearly given. The long incubation of rubella (a name for *rötheln*, worthy of general adoption), and the short persistence of its infection, given at three weeks, bring the alliance of this disease to rubeola, or true measles, into close relationship; rubella is shown to be distinct from both scarlet fever and from measles. Whooping cough has a long incubation assigned to it, chiefly on account of the delay in the development of characteristic symptoms; as infection will persist while either cough or whoop remain, the infectious period must be very variable, mostly six weeks—often much longer. A curious instance is given under varicella, of how infection persisted five weeks in a case where a subsequent psoriasis delayed the completion of the chicken-pox cicatrix. No doubt it is a good rule in both variola and varicella, that not only should the crusts have separated, but the cicatrises be sound before a convalescent is allowed to mix with the susceptible; but we have often seen this rule departed from, even as early as ten days after chicken-pox without ill results, and should be disposed to put the termination of infection closer to the subsidence of the fever in most cases of this disease than in any other. This one case of Dr. Ashby's is, however, quite sufficient to "give us pause."

We dwell on this one point touched upon in these sections, because it is impossible to note many with anything like adequate fulness. To retrace our steps, we will extract a few words from the treatment of whooping cough. After a caution as to the necessity for guarding against cold, and the risks of intensifying the catarrhal stage of the disease, there is a line or two in favour of the two-room treatment, and the following: "There can be no doubt that the attack is rendered more intense and protracted by rebreathing the infection, as well as by a fresh catarrh being set up. Except in the warmest weather, the patient should be confined to his rooms in the house the whole time the disease lasts, as long as any 'whooping' is present, and as long as râles or rhonchi are heard in the chest. Too great care cannot be exercised here; the bronchial tubes and lungs remain exceedingly sensitive to cold, and many severe attacks of pleuro-pneumonia have resulted both in old and young from a chill caught at out-door games, or from having gone to the seaside for change of air. Children are much better at home until well over the attack, not only for the sake of others, but for themselves; and the pleadings of the friends for change of air must be sternly resisted until six weeks, at least, from the commencement of the whooping" (p. 267). No reference is made to second attacks. Protection is probably secured for some years by a first attack, and the author commences by saying, "There is no disease which is more certainly infectious than whooping-cough." To measles a high degree of infectiousness in the early stage is ascribed. From an experience apparently less extensive than the author has of scarlet fever and whooping-cough he ventures a statement at variance with most authorities—that "second attacks of true measles are not uncommon" (p. 228). He also, under the heading "Treatment," probably follows some other writer in admitting antimony and aconite as possibly useful, though under restrictions, in the earlier stages of this self-limited eruptive disease. Scarlet fever is more fully and very ably described. The complications and sequelæ are separately treated of and well given, as is the short section on "Morbid Anatomy." It is here noted that the micro-organisms found in the kidney are similar to those of septicæmia. The large number of cases of scarlet fever coming under the author's observation leads him to the conclusion—"second attacks are rare." Relapses or reinfections are barely allowed for, and some instances are considered doubtful (p. 213).

Mr. Wright's work on "Hip Disease in Childhood" has already brought him favourably before the medical profession. We have only to turn to the commencement of his chapter on this subject in the present volume to see how intimately it is associated with tuberculosis and the deposit of tubercle elsewhere, and must defer fuller notice of his work until a more systematic review of the book from beginning to end can be completed. First, we must direct attention to the real importance of the opening chapter on "The Physiology of Infancy and Childhood." It is not enough for the study of the diseases of infancy to know the symptoms of special illnesses, the natural history of each, the early signs of ingress, and their after-consequences; but the normal variation of pulse, respiration, temperature, growth and weight of the child at different ages and under varying conditions, must be studied and known. Any gain in certainties of this kind, however slowly won, steadily advances the art of medicine. Here we have the rate and ratio of pulse and respiration, how they slowly alter with development, and how rapidly they revert to the infantile type under disturbing causes; then the development of other infantile powers by which we may judge of their arrest by disease, and the rate at which they advance to the normal state when the illness is over. A section on psychical phenomena (p. 8) is worthy of some additions. An infant may learn to hold up its head at two months, but it could hardly be trusted to support and balance it till three months old. At seven to nine months the child can sit up; it will soon try to support itself by a chair, and not wait for three or four months before trying to walk. Children soon learn their own ability and strength in muscle and bone. Talking is learned in the second year, but it is seldom that any account or relation of

experience can be expected before the end of the third year. The body weight—its relation to growth and the importance of the two taken together—as witness of the healthy progress of children, is very well given and insisted on. In the table of corresponding heights and weights it would seem that the rough weight, taken with the clothes on, has been followed.

Dentition, here treated of, leads us to the subject of "Hygiene and Diet of Infants and Children," and opens the following chapter, the fourth, on "Diseases of the Digestive System." The influence of rickets in checking dental development is further given at pp. 42-43, and the effects of other diseased states mentioned elsewhere, p. 353. It is pointed out that the transverse grooves on the central permanent incisors will be near the edge when caused by disturbed nutrition in early childhood, and lower down if from illness at two or three years of age. Convulsive seizures occurring in the first dentition will thus leave their marks on the second teeth, or the effects of whooping-cough or measles be seen on then, or on the first molars; yet in one place, p. 12, these defects are attributed more to a possible local stomatitis than to well-known general causes. Some remarks (p. 45) as to lancing the gums during teething deserve quotation: "Much controversy has arisen from time to time with regard to the use of the lancet, and the propriety of employing it in assisting dentition. . . If the mucous membrane over the tooth is red, swollen, and tender, and the edge of the tooth can be felt, much pain and discomfort will be spared the infant by its use. . . . . The relief afforded is due in all probability to the local loss of blood, as well as to the relief of tension in the gum. That it has been done often unnecessarily, and that many troubles are attributed to dentition that have no connection with it, is no argument against the use of the lancet in proper cases." The rules of diet given are good and sound throughout. One passage, at p. 42, is not as clear as it might be that to defer the addition of fish, fowl, or meat, to a child's food until after the first double teeth are through, is to fall into a vicious circle; for if this diet is right for a child of a year and a half old with molars, it is sooner required when they are slow to appear.

The bearing of disorders of the digestive system in early childhood on subsequent disease receives a fulness of treatment in the work before us commensurate with the importance of the subject. Not only in the seven or eight early chapters of the book, but in chapters xi. and xiii., under "Larygismus Stridulus," p. 149; again at p. 175, under "Broncho-Pneumonia;" and at p. 205, under "Chronic Tuberculosis of the Lungs;" also in the chapters on "Tuberculosis," "Rickets," and "Diseases of the Nervous System," weighty evidence of this is to be found. If the term "athrepsia," used at the beginning of chapter vi., could sink deeply into our medical nomenclature, carrying with it a full appreciation of the causes and results of a chronic gastro-intestinal catarrh in infancy, many of the dangers and anxieties of illness in childhood would be greatly lessened. The term "simple atrophy" is less applicable; it puts the result for the cause; it withdraws attention from the inter-current disturbances of health, such as the broncho-pneumonia, or diarrhœa with fever, or the nervous symptoms, though unaccompanied by fever, and attributes them to tuberculosis. Nor is the common name justified until general wasting, with persistent low temperature, and the final and irremediable atrophy of the gastro-intestinal has set in. But a disease fatal in this way to children under two years of age may begin, as the authors point out, in various ways at a later age, mostly as a chronic intestinal catarrh.

This, as stated at p. 78, "is rarely followed by an atrophic condition of the glandular apparatus of the stomach and intestines, but takes rather the form of habitual indigestion than anything else. It is, however, apt to be exceedingly chronic in its course and to be followed by various evil consequences, the most serious of which is tuberculosis of the lymphatic glands, or there is a constant state of health below par, which in itself is a source of danger." The evils resulting from chronic catarrhal affections of the mucous membranes are further insisted on as leading to tuberculosis of the mesenteric, mediastinal, or bronchial glands, or to chronic tonsillitis and enlarged glands of the strumous type; or "the symptoms of rickets become grafted on to those of a chronic catarrh of the bowels" (p. 78). The course of the disease is often intermittent; the bowels become confined, with inter-current attacks of vomiting and diarrhœa, evening fever, and night terrors, or grinding of the teeth. Subacute cases constitute what was called "infantile remittent fever" (p. 79). When mistaken for mild typhoid fever we have known it lead to a severe form of chronic obstruction of the bowel, from retained fœces in palpable masses, in a girl of five years old. We quote the section on "Diagnosis:"

"The disease most likely to be confounded with chronic intestinal catarrh is tuberculosis of the mesenteric glands, or the early stages of tubercular meningitis. During the first three or four years of life, it happens very frequently that infants or young children are thought to have 'consumption of the bowels,' because they have capricious appetites, 'pot bellies,' and have lost much flesh, when in reality they are suffering from a chronic intestinal catarrh. That the diagnosis is often difficult is only what is to be expected when it is remembered that an intestinal catarrh of more or less severity is the exciting cause of mesenteric tuberculosis; and in an advanced case, it may be quite impossible to say if a tuberculosis of the glands has supervened. Mesenteric disease is, however, much less common than simple intestinal catarrh, and is infinitely less so during the first six months of life than gastro-intestinal atrophy. Any evidence of tubercle in the lung, or enlarged veins of the surface of the abdomen, or the detection of rounded masses by palpation in the abdomen, would favour mesenteric disease. In older children the fact that those suffering from intestinal catarrh grind the teeth, are restless at night, are subject to night terrors and headaches, is sufficient for most parents to become alarmed, fearing that the child is commencing with tubercular meningitis."

Among the predisposing causes to this condition, if injudicious feeding must claim a first place, zymotic diarrhœa, as shown at p. 69, is certainly a most potent one, and may be a reason why the direct fatality of summer diarrhœa in the first half-year of infantile life so far exceeds the peril incurred from it in the second half year of age.

Before quitting this part of the subject, we will refer to the section on "Convulsions," p. 44. "It may be taken for granted that no healthy infants suffer from convulsions; those who do are either (we add *ill-fed*) rickety, or the children of neurotic parents, and inherit a tendency to nerve disturbance." A good example of how well in this book surgical detail supplements the medical treatment is seen under tonsillitis (pp. 54, 55), where tonsillar hypertrophy is shown to retard growth; a difference of several months' growth was observed "in twins, one of whom had enlarged tonsils, the lost ground being rapidly regained

after removal of the glands." We are disposed to accept the verdict of the surgeon as given here, that "the only efficient mode of treatment is by removal." As before mentioned, it is to the surgical part of the work that most of the engravings are assigned. There is one at p. 50 showing the deformity that may result from an attack of *Cancrum oris*. The complete remedy possible from a plastic operation is very properly left to the imagination. This course might have been followed at p. 472 with fig. 78—the only illustration we wish absent. Fig. 40, at p. 280, is admissible, as showing the extreme effects of nævoid growth. All the illustrations of the deformities due to rickets, and to bone and joint diseases, and to tumours, are of distinct value. In many cases we are not only told what to do, and how to do it, but the consequence of doing or not doing what is recommended is graphically put before us. In fact, the advantages resulting from the combination of medical and surgical details are manifold and obvious, and we have in one volume—open it or refer to it where we will—a most useful and thoroughly practical handbook of the diseases of children. The published price is one guinea.

(*To be continued.*)

On the Diseases of the Kidney amenable to Surgical Treatment. By David Newman, M.D., Surgeon to the Western Department (Out-patient Department); Pathologist to, and Lecturer on Pathology at the Glasgow Royal Infirmary. London: Longmans, Green & Co., 1888.

One of the results of the modern post graduate lecture development is the continuous addition of unnecessary volumes to the already over-stocked market of medical literature. The lectures themselves are probably of service to those who hear them, who may be unable to keep *au courant* with the rapid advance of medical knowledge; but the repeated publication of treatises, which are alike except in the names of authors and publishers, is much to be regretted.

Dr. Newman's volume reads rather like the work of a pathologist than a surgeon, and although the lectures are full of interesting information we venture to think that the author might well have "said his say" in less than four hundred and fifty-seven pages. The scope of the book is comprehensive to the extent that it appears to include every disease which affects the kidney, except the group known as "Bright's." Broad distinctions cannot be drawn between the medical and surgical diseases of any part, but whether kidneys, which are healthy but floating and movable, sarcomatous, carcinomatous, or angeiomatous, may be properly regarded as amenable to surgical treatment is even yet extremely questionable. The contents of the volume are arranged as six lectures. The first is devoted to malposition, with or without mobility, the latter group being treated of under the two separate divisions of movable and of floating kidney. We agree with the author that mobility is more common than is generally supposed. He gives 1.8 per cent. as the number in his own observations. The various views and theories are discussed at great length, great use having been made of Landau's monograph on the subject. Dr. Newman speaks more favourably of the permanent benefits of nephrorraphy than our own experience of the operation would justify.

In lecture two, on general symptomatology, attention is limited to the presence of blood or pus in the urine, and the existence of pain or swelling in the renal region. These symptoms are carefully considered, and the chapter is an extremely interesting and valuable one.

Section three deals with diseases characterised by accumulation of non-inflammatory fluid. We doubt the wisdom of including cases of dilated ureters, sequential to urethral stricture, enlarged prostate, etc., in the class of "acquired hydronephrosis." They are so entirely different from those large cystic dilatations familiar to us as "hydronephrosis," which are usually unilateral, and which only are "amenable to surgical treatment." The author advocates treatment by lumbar incision and drainage, with subsequent nephrectomy when necessary. Carefully prepared statistical tables of all published operations are affixed to each chapter, and form one of the most valuable features of the volume.

Chapter four is devoted to diseases characterised by simple inflammatory changes, with accumulation of inflammatory products, and contains more than a hundred pages. It treats of every variety of suppurative disease, both within and around the organ, as well as of renal calculus. It is discursive in its arrangement, tedious in its length, and contains much which may be found in elementary text-books of medicine and surgery.

The fifth lecture opens with a long discussion on the general question of tuberculosis, which would be more in place in a manual of pathology. It is still an open question whether renal tuberculosis is amenable to surgical treatment. The latter part of this lecture takes up injuries and their treatment, and is of much more practical use.

The final chapter calls attention to no less than twenty-four different kinds of tumour which *may* affect this organ. The kidney is, nevertheless, not very liable to be invaded by new growth at all. The author describes an original method of collecting the urine from one kidney, and figures an instrument designed by himself for this purpose. We are disappointed to find that even in his hands the results are not always encouraging.

Surgical operations are dealt with in the concluding thirty pages, and are the least satisfactory part of the whole volume. Speaking of lumbar nephro-lithotomy, he says the surgeon "should not be satisfied either that no stone exists or that nephrectomy must be performed, until he has made such an incision into the kidney as will open each of the calices." We fail to understand how any incision could be arranged so as to open "each of the calices" of kidneys, whose interiors we have especially studied with reference to this subject. If one incision is made into a calyx at the lower end of the viscus, the other calices may be examined by means of a small sound passed through the opening. The book is well got up, and is set in a type which is clear and easy to read. Jordan Lloyd.

Short Notices.

Medical Handbook of Life-Assurance, for the use of medical and other officers of companies. By John Edward Pollock, M.D., etc., and James Chisholm, Fellow of the Institute of Actuaries, etc. London: Cassell and Company.

This work will be appreciated by medical men who have to examine for insurance companies. It is a book which supplies a want.

The Provincial Medical Journal,
AUGUST, 1889.

Dr. Paul Le Gendre in the *L'Union Médicale*, June 25th, 1889, presents us with a very able summary of the latest views on the pathology and treatment of diphtheria, of which the following is an abstract. In his recent book, "Diphtheria: its Antiseptic Treatment," M. Renow characterises by four epithets the state of mind of some medical men when the treatment of diphtheria is discussed—scepticism, despair, indifference, enthusiasm; and he adds that medical men very frequently pass through all the different stages, and that diphtheria justifies all these states of mind. Dr. Le Gendre does not think that indifference can be justified, in view of a malady so frequently seen,—nay, that ardour with the struggle should be increased by the progress made in our knowledge of its etiology and pathology. The prophylaxis is singularly cleared up; we know that a microbe grows on the nasal, buccal, pharyngeal, or laryngo-bronchial mucous membrane, which is deprived at some point of its epithelium, by acute catarrhal inflammation. We know the principal biological characters of this microbe, and that it is most frequently carried—though not exclusively—by the intermediary of persons, and not by the air. According to an hypothesis of MM. Roux and Yersin, this microbe remains in certain individuals inoffensive on the bucco-pharyngeal mucous, as long as it is healthy, the pathogenic action of the microbe taking effect only when the mucous is inflamed.

The therapeutics are clear. We have to institute an antiseptic treatment of the least catarrh of the air-passages in children, to prevent the microbes from finding a resting place; to look after the naso-pharynx, and to keep the buccal cavity in a state of asepsis. We must, moreover, with perseverence carry out the complete disinfection of all places where diphtheritics are, destroy all objects which they have touched, and which cannot be conveniently sterilised. When the fundamental precepts of prophylactic antiseptics have sufficiently penetrated all the medical profession, and not merely its *elite*, the non-medical public will better regard the dangers which they now are indifferent to. The frequency of diphtheria will certainly diminish, as will, without doubt, that of tuberculosis, if medical men in treating these diseases will instruct patient as to antiseptics. Leaving prohylaxis, Dr. Le Gendre says that the recent discoveries of MM. Roux and Yersin should inspire courage in the physician, even as to its therapeutics. We know now with scientific precision that diphtheria evolves in two stages—local infection by microbes, and consecutive general intoxication by a chemical poison fabricated by the microbes on the surface of the false membrane. It is true that the first stage is short, but it always exists, and diagnosis at as early a stage as possible therefore becomes important, so as to destroy the microbes before they have time to saturate the economy with their poison. But here care is required, it is not prudent, to break up the tissue, as thereby the microbe could better enter. There are two views, one that of M. Renow, who advocates leaving the false membrane alone; and that of M. Guelpa, who pursues the microbes without mercy even into the most inaccessible places.

1. M. Renow, who wrote before the publication of the works of MM. Roux and Jersin, states in his book that when we see diphtheria the microbe has already invaded the organism, and we must seek for it in the blood. He rejects all cauterisation and meddling with the false membrane, in which he sees a precious element of diagnosis and prognosis from day to day. M. Renow does not even approve of irrigation of boric acid, introduced by Dr. Le Gendre. He proposes to treat his patients by antiseptic air, by phenic vaporisation. M. Renow keeps his patients in a temperature from 20 to 22 R., and the atmosphere is saturated with phenic acid solution, the proportion of phenic acid being calculated according to the cubic space of the room. The limit is one gramme of phenic acid per cubic metre in every twenty-four hours. The rest of the treatment comprises alimentation, tonics, sulphate of quinine, and tracheotomy in case of need. The false membrane is not touched. M. Geffrier, at the Hotel Dieu, Orleans, has tried the method, and reports in its favour. Some practitioners at Saumur have also adopted it. At Nantes M. Bonamy prefers a solution of eucalyptus. Dr. Le Gendre disputes M. Renow's view of the pathology, and avers that the microbe remains on the mucous surfaces, but that the chemical poison is diffused. He also points out the danger of phenic poisoning from this method of treatment.

2. M. Guelpa acts in a very different manner from M. Renow. He pursues the microbe with vigour into the most innermost recesses, irrigating every quarter of an hour during the day, and every half hour during the night, with a solution of perchloride of iron, five or ten per 1000. He is even in favour of preventive tracheotomy, and even of trepanation of the maxillary sinus. When diphtheria has invaded the nasal fossæ, Dr. Le Gendre does not think that the latter process will find much favour, though tracheotomy may be necessary in certain cases. There is an objection to this irrigation, as it deprives the patient of sleep; moreover, the solution of perchloride is weak, and the antiseptic properties doubtful.

The eclectic plan of treatment recommended by Jules Simon is next passed in review. M. Simon recommended every hour during the day, and three hours during the night the following solution:

Salicylic acid	0.50 to 1 gramme
Alcohol	qs. to dissolve
Glycerine	40 grammes
Infusion of eucalyptus	60 grammes.

This is applied with certain force, so as to detach any fre membrane, though without excoriating the adjacent mucous. When the membrane is thick and adherent, it is touched with equal parts of perchloride of iron and glycerine. Every two hours this plan is followed by warm irrigations

with lime water, boric solution, Vichy water, rarely with phenic acid. M. Simon also uses—according to the age of the child—gargles, pulverisation, etc., burning in the chamber tar and eucalyptus. Besides alimentation and tonics he gives internally perchloride of iron (ten to twenty drops) every twenty-four hours in grog or beef tea; for children over five years of age using cubebs and copaiba.

Dr. Le Gendre gives his own treatment, carried out at the Hospital des Enfants Malades. In 1887 he ordered the following treatment: he ordered three or four times a day the whole of the false membrane to be touched with sublimate in alcohol $\frac{1}{100}$; every two hours free irrigation, followed by pulverisation, with a saturated solution of warm boric acid, 4 to the 100. The frequency of the irrigations may be increased. In 1888 he tried the medicine recommended by M. Ch. Bouchard, swabbing the whole surface of the false membrane with the following solution:

Naphthol	5 grammes
Alcohol	5 ,,
Glycerine	100 ,,

This treatment is borne very well, and is very refreshing; there is no inflammation, and the naphthol remains adherent to the diseased surfaces, exercising its antiseptic properties. Dr. Le Gendre thinks that the phenols with camphor or oil are superior to mercurial solutions, and especially camphorated phenol. The method of M. Gaucher meets with favour. He has modified his formula:

Tartaric acid	1 gramme
Pure phenic acid	5 grammes
Alcohol @ 36	10 ,,
Camphor	15 ,,
Oil of sweet almonds	20 ,,

To obtain a clear solution dissolve with heat, with care, the phenic acid, the camphor, and the alcohol; then add the tartaric acid and the oil. This solution must be thoroughly applied morning and evening, the false membrane being removed, and the parts well touched, subsequently employing the warm saturated boric solution. Excellent results have followed the employment of M. Gaucher's method, and Dr. Le Gendre is able to testify to good results.

"The Exposure of Electricity" is the name of a pamphlet made up of the letters and articles which have appeared in the columns of the *Electrical Review*. The profession owes that journal a debt of gratitude for the manner in which it has tackled the charlatans who are living by this form of quackery. In return the profession ought to purchase the pamphlet, and circulate it in every city, town, and village—thus the advertising quack will be paid back in his own coin, and obtain a publicity he did not bargain for. With one or two exceptions the medical press has not given much assistance to the suppression of electrical quackery. This may be explained in this wise: the medical press is wearied of the subject of quackery. No sooner is one humbug exposed than another starts up. The public, we believe, like being gulled; they so readily swallow every bait offered them. The profession can hardly check the spread of quackery, and medical editors having better materials for their readers, do not care to waste the space in their papers by going over the old ground. The form of humbug adopted by the electric fraternity may strike electricians as being worthy of exposure, but it is only one form of charlatanry. Look at any advertisement sheet; read the list of quack remedies, all professing to do what the electric quack promises to do. We cannot tackle all the peripatetic disease curers, or expose their pretensions. So much in explanation of the silence of the medical press. Now for the pamphlet. The victims who are gulled by cleverly worded advertisements do not, as the author says in his preface, see the scientific organs in which are exposed the worthlessness of the goods advertised, and the charlatans flourish in spite of the efforts which are continually being made to scotch, if not to kill, the many headed hydras who prey upon suffering humanity. Since the appearance of the pamphlet by "Detector," which dealt with the museum quacks and syphilis curers, we have not read a more convincing and thorough exposure than this one. With an amount of daring, worthy of all praise, the authors have boldly tackled firms prominent in the field, and they have persisted in their attacks, though they have been threatened with law suits, threats which have ended in smoke, because the quack dreads the ordeal of law and cross-examination, which will bring out the previous history of the advertiser, and facts which are discreetly kept in the background. We are let into the secret of some portions of the inner life of electrical quackery; we are shown how the system is worked; we have letters from the dupes who have paid their three and five guineas for instruments estimated to be worth as many shillings. Electricians of repute have examined the construction of the patent belts, and have pronounced them to be worthless. The curative agency resolves itself into faith and flannel. It would be highly desirable if a test action could be brought into the courts—thus, if some one who has purchased a three guinea belt or machine would bring an action for obtaining money under false pretences. This was done, as was mentioned in the pamphlet, in the case of an individual who advertised a sewing machine which turned out to be a clever swindle. By means of the test action scientific opinion could be brought to bear upon the value of the belts and the appliances, and a serious hole would be made in the bubble. Dr. Steavenson has written very strongly in our columns on the cruel deceptions practised by the clever quacks who have taken up electricity as their bait, and we have helped as far as possible to expose this genus. If our readers desire to help on the crusade they should write for copies of the pamphlet to Mr. Jerritt, Ivy Bridge.

We published in the last number of the *Journal* a long letter from Dr. Rentoul, proposing the establishment of a complete medical service for England. It is an honest attempt to bring order out of chaos, and it is significant of the awakening of the profession to the importance of the proposals that it has been taken up by the British Medical

Association, and discussed at its branches. The industrial classes have been brought up to regard free medical advice, if not as their birthright, certainly as something they were entitled to, and they have been gratified. Hospitals, and dispensaries have been at their disposal, and free medical advice has been the order of the day. A certain number of the industrial classes, not desiring to accept free medical aid, formed themselves into clubs or combinations, and paid for medical advice, and they were comparatively liberal. They gave the surgeons who attended them 2*s.* 6*d.* a year per member, finding, at this price, medicines, appliances, etc. In certain towns, all these clubs combined, and had one medical man to whom they paid an annual stipend varying from £150 to £200 a year. The work done for this salary by some of the men who have been engaged in this service was simply slavery. The industrial classes brought up in the school of political economy have conducted all their transactions with the medical profession on the strict lines of political economy, as illustrated by the law of supply and demand. They have offered their private lodge surgeoncies at 2*s.* 6*d.* per head per annum, and there has been keen competition for these appointments; active canvassing, as in the case at Wigan, went on to secure such positions. They had numbers of applications for the medical officership of the amalgamated societies. Besides this, they could always depend, in case of need, upon the local hospital or dispensary, so that the industrial classes have had at their disposal, not only a cheap system of medical advice, but a highly efficient one. This system was supplemented by another one. The majority of the industrial classes do not belong to clubs; for this class the provident dispensary was opened, and we have now every kind of machinery to bring medical assistance within the reach of the poorest class of industrial workers. We have the shilling dispensary, and we have the sixpenny dispensary, and the wonder is with all this cheap organisation, and with all the free medical advice, how medical men are able to live. It is the boast of medicine that it is conducted on lines which are opposed to every principle of political economy. We take on our shoulders the individual relief of suffering humanity; we give our services gratuitously for the good of humanity. Once a year there is a general vote of thanks passed to the profession by the hospital governors, who for a year have been lifted up into a position over our heads, and who owe their existence as governors and philanthropists to our skill. On this one day (the annual meeting of the charities) there is a vote of thanks to the medical officers. After the annual election, the governor who gives his £1 1*s.* 0*d.* a year regards the medical officer as a kind of servant of the institution, and we believe that so far as the outside public are concerned, the governor who gives £1 1*s.* 0*d.* a year is looked upon as a much more philanthropic man than the surgeon who daily visits the hospital, and gives for a whole year that which is priceless. Surrounding the whole subject of hospital medical relief and free relief, there is a mass of contradictions; the best traditions of the profession must not be disturbed. "The poor are always with us; the poor when sick must be attended to for nothing." This is the key note to the position, and this is the work which must be carried on. The abuses which have crept in, the pauperisation which has followed from the abuses, are the incrustations which must be removed. The poor are not the industrial classes; the poor are not the people we see in the waiting rooms of our general hospitals, or occupying the beds; so that we are not running counter to the best traditions of medicine by advocating a revision of the conditions under which medical relief is at present given. The altered conditions of modern life, and the increased opulence of the working classes, must be taken into account. In considering any scheme we must also consider the interests of medical men and their families. Hitherto, the industrial classes have alone been considered. They have pointed out the way in which wages have to be kept up to such a level that the happiness of the greatest number of workers shall be preserved, and by which the weakest shall be protected. By means of trade unions they have decided that men shall work so many hours a day, and at such wages; they have in other ways limited and protected labour. In a profession we cannot adopt trade unionism, though we have every right to consider the interests of the 100,000 persons who are dependent upon medicine (this of course includes men, women, and children). The state of the medical profession, as revealed by numerous letters and articles which have appeared in the journals during the last few years, is a very alarming one. We are suffering from the effects of unfair competition. Our charity is abused; pecuniary results are inadequate. We are as willing as ever to attend the poor, but we must distinguish, and have it defined who the poor are. It is only by discussion and by free ventilation of the question that we can arrive at a satisfactory solution, and we therefore hail with satisfaction the reception given to Dr. Rentoul's scheme by the British Medical Association. Free discussion at the branches will bring medical opinion to a focus; from the branches the subject must go to the council or general association. By concerted action alone can we succeed; but at the same time, what we decide upon must be worthy of the dignity of the profession. We do not desire to overtax the industrial classes, but we certainly ask for justice, and for fair remuneration.

Some years ago, we believe somewhere about 1866, the *Pall Mall Gazette* published under the heading of "A Night in a Workhouse," by the Amateur Casual, a very sensational description of the actual state of our tramp wards. The papers created some excitement at the time, and we believe led to great reform in the condition of the refuges of the poor—the workhouse tramp wards. This system of exciting attention to our social grievances has its advantages. It is an old saying "that one half the world does not know how the other half live." By means of such descriptions by the press, the world is let into the

secrets of life in that larger world which has to live under such miserable conditions, that life is really not worth living. The cause of humanity is advanced by these exposures. The amateur casual's articles were read by thousands, to whom the name even of workhouse was hardly known; and by a few graphic paragraphs, the conditions of life for the tramping poor was at once revealed as in a picture from a camera. We do not remember reading any better description of the state of the homes of the working classes than that which has appeared recently in the columns of a Manchester Sunday paper—the *Chronicle*—and we may compare the descriptive writing for power with that of Mr. Greenwood. The condition of the houses of the Manchester workers are revealed with microscopic minuteness by an anonymous chronicler, and we would fain hope that now that the citizens of that wealthy city know that there are such rookeries in existence in Cottonopolis, some attempt will be made to sweep them away, and erect buildings in which the workers may live in decency; may grow up in health, and by increased toil give back to the community double interest for any outlay involved in the erection of new houses. It is not pleasant for a wealthy town to have this exposure, but it is childish to ignore stern facts. This *Sunday Chronicle* does not find favour with some of the press or the laity, but it must find support from all who are really interested in the spread of sanitation, and in the elevation of our working class population. Those who know anything of the inner working of some sanitary committees—who know the class on these committees—are aware that there is a *vis inertiæ* to be overcome; oftentimes a vice, too—the vice of wanting too much interest for rotten property, so that self-interest comes in, and sanitary reform is prevented. Medical officers of health may recommend alterations in premises, new closets, new drainage, the destruction of unhealthy dwellings, but these recommendations are shelved—in the interests of property owners. The indignant and independent journalist, who with pen and pencil has described Manchester as it is, should have had a vote of thanks passed to him by the Town Council for doing the sanitary work of the town in such an efficient way; for exposing the sore places, in order to heal them; and from the working classes he should have some more solid recognition. There may be in these articles touches of sensationalism, and here and there the colours may be laid on with too heavy a hand, but the sun pictures which have accompanied the articles cannot be accused of exaggeration, and we have in these sketches, and in the measurements which accompany them, a text which requires no comment. Tenement property pays a much higher rate of interest than good property. Nothing is spent on it, and so long as the walls hold together, and there is a decent external appearance, there is no outcry. The property owner who lets houses at £40, £50, or £100 a year has many calls upon him, and he has to set his house in order before he lets it. The tenement house as it existed in London, and as it still exists in many of our provincial towns, so faithfully described in the papers we allude to, is a blot upon civilisation. The wonder is that the working classes themselves are so apathetic about the condition of their homes, and that the working class leaders have given so little attention to it. Any demagogue could at once get up a large meeting to denounce the House of Lords; to disestablish the State Church; to protest against Bulgarian atrocities, but we very much question whether he could secure an audience to consider what is of more passing and vital importance—viz., the housing of the working class. Charles Lamb has written one of his best essays on homes that are no homes; all that is best in life is crushed out by the environment in which men, women and children live in our crowded cities and towns. The home should be the centre of the nation's life; it is the cradle of our people; but in such houses as exist, which are called homes, nothing but degradation of the people can result. It is no wonder that we have so many decrepid and deformed children; that we have so much tuberculosis; that we have so much disease, and crime, and misery—nay, the wonder is that we have not more; and that we have such a high death-rate, when people have to live under conditions which set at defiance the laws of nature. The remedy rests with the people themselves, and we cannot free ourselves of responsibility by throwing the blame on the corporate bodies who rule and manage municipal affairs. As soon as the people want good homes they will have them. The magnificent municipal buildings, the art gallery, the parks, the theatres, the churches, the palace of recreation, are all in their way useful and creditable; but unless the majority of the people are properly housed, all these indications of wealth and progress are but as the guilding on the "whited sepulchre."

Annotations.

"Forsan et hæc olim meminisse juvabit."

BRITISH NURSES' ASSOCIATION.

The British Nurses' Association, established with very excellent aims, has met with considerable opposition, but into the merits of the dispute we do not at present intend to enter; we desire only to draw attention to the amenities of medical journalism as illustrated even at the present day. That there should be difference of opinion on all professional subjects is but natural, and it is by difference of opinion that progress takes place. It is too late in the day for any journal to say, "I am Sir Oracle, and when I open my mouth let no dog bark." The days of authority in medicine are over: each question must stand on its own merits: the personality of individuals must be left out. There was a time when we were, in a certain measure, influenced by the personal equation of individual teachers whereby the advance of medicine was stayed; but we have emerged from the stage of babyhood, and we cannot any

longer be dragged at the wheels of personal authority. Miss Lückes, Dr. Sansome, Mr. Burdett, and others, do not approve of the British Nurses' Association, even though it is supported by Princess Christian and other persons held in high esteem; they are perfectly justified in expressing their views, and in criticising the proposals which affect the nursing profession, as well as the medical. Boycotting is out of place in the scientific world, though, judging by certain editorials we have read recently in connection with this controversy, it would seem to find favour with a journal which at one time had a great influence with the profession. The boycott would be very useful as a one-sided measure when your opponents disagree with you; cease to subscribe to a paper which does not favour your own views, and you will narrow your mind and obtain a truimph—for your own views.

THE MEDICAL SICK AND BENEFIT SOCIETY.

We would direct attention to the Sixth Annual Report of this Society, and we trust that the report will be read in full by the younger members of the profession. The first quinquennial valuation made by Mr. Neison shows the financial position of the society, and the management is to be congratulated upon the handsome surplus found to exist at so early a period in the history of the organization. The invested capital amounts to £32,247 12*s.* 1*d.*, and the total fund to £32,561 13*s.*, so that it will be seen that most of the capital is invested, and invested in securities of the soundest nature. The increase in the funds may be seen from the following table:

Date.	*Amount of Reserves.*				*Increase on Years.*			
	£	*s.*	*d.*		£	*s.*	*d.*	
June 30, 1884	1,434	16	3	.....	—			
June 30, 1885	6,433	0	10	.....	4,998	4	7	
June 30, 1886	11,330	7	6	.....	4,897	6	8	
June 30, 1887	17,645	3	0	.....	6,314	15	6	
June 30, 1888	24,694	17	9	.....	7,049	14	9	
June 30, 1889	32,561	13	0	.....	7,866	15	3	

The number of members at the close of the financial year was 985, and there have been only two deaths during the year. This did not touch the assurance fund, as these two members were only insured for sickness. The expenses of management have been under five per cent. Payments were made during the year to 130 members for 636 weeks and six days' illness, and the illnesses have been very diverse in character. The secretary, Mr. Radley, 6, Wynn Road, will give all information.

CAMPS FOR POOR CHILDRFN.

No better work could be engaged in than that of sending children into the country, or to the sea-side, and putting them into tents, so that they may be enabled to breathe pure air. The children who live in the back alleys and slums of large towns have but little chance indeed of sharing in any amusements save the making of mud pies; they have not been lifted into an atmosphere in which there is organisation, so that even a brief visit to a camp will waken up elements in the children's nature which will afterwards bear fruit. The children will in camp learn to see the value of order, cleanliness, what it is to play intelligently. The young men who have taken up these camps are deserving of support, and it speaks well for our aristocracy that they have been one of the first to embrace the movement.

THE MODERN INTERNE.

Dr. John S. Hawley, New York, describes as follows the learning of the modern house surgeon:

Erudite in physiology and advanced bacteriology, the interne talks pathology 'till you're deafened by the din,
And of differences essential between high and low potential, and of diagnosis differential of diseases of the skin.
All the signs auscultatory, cardiac, respiratory, are arranged in category his active mind within.
From pyosalpinx gonococcic he gestation that's ectopic tells by murmurs metroscopic, and he knows when it is twin.
He knows pelvic cellulitis from acute oöphoritis, and from hernia, adenitis, be the patient fat or thin,
Or a pachymeningitis from a poliomyelitis, and a typhlo-enteritis at its very origin.
And he knows an epileptic from a seizure cataleptic, and a coma apoplectic from one caused by drinking gin.
Also knows tuberculosis from actinomycosis, and how enemoscoliosis doth distort the youthful shin.
He describes the diabolic agony of renal colic; how aphasia embolic rests the weary, jaded chin;
How luxated hip reduction you achieve by circumduction after ad- and then abduction, if with flexion you begin;
And of kolpoecpetasis, dysmorphosteodiaclasis, and of teleangeiectasis many startling yarns he'll spin.
Of nephritic amaurosis, also symblepharosis, and of intermittent ptosis, which to winking is akin;
Of his skill in pædiatrices, and in modern psychiatrics; of *vis Naturæ medicatrix*, which the palm will always win
In the strife with mind revealers, and with Christian science healers, or with long-haired faith-cure kneelers, who say cancer is but sin;
With interviewers theosophical of Indian ghosts apocryphal, who from climates hypertropical come to practise medicine;
With those with eyeballs staphylomal, who in trances hippodromal voice the accents catacombal of some sainted mandarin,
Who prescribes, for use internal, roots you dig with rites infernal at the moment mid-nocturnal with a piece of rusty tin.
He detects each spinal lesion, every visceral concretion, from that ammoniaco-magnesian to that of pure cholesterin;
Describes the splint of his invention by which he keeps up firm extension, attaching rubber bands in tension to a stationary pin.
Armed with weapons stethoscopic, sphygmographic, microscopic, like a very philosophic, scientific palladin.
Seeks he ulcers duodenal; rends he pectorals trichinal; spears the abscess circumrenal with hypodermic javelin.
He's no Dædalus with wings rheumatic, who, as in the soup his son erratic learns a lesson aerostatic, flies low down with rueful grin.
But, like Icarus, he's sophomoric; his flight at first is meteoric, 'till solar beams so thermophoric melt from his wings their paraffin,
For the interne, ill-supported by his knowledge well assorted, actually as sprains reported the first three fractures he brought in.

AN AUTOMATIC SIGHT TESTING MACHINE.

Automatic machines have undergone many developments during late years. We have now on this principle weighing machines, machines for distribution of post-cards, photos, cigars, sweets, and we shall shortly have in the public schools an apparatus for testing vision. The nimble

penny caught in this way amounts in the aggregate to thousands of pounds, and we may expect a still further development of these machines for the supply of trifling articles. We have been favoured with a private view of the Bruce Green de Woolfen's sight-tester, and we offer a description of it. There is the usual case, somewhat after the model of the weighing machine, but on the front face are two eye-holes, with depression underneath for the nose. You place a penny in the slot, press one foot on a pedal, look through the eye-holes, and by turning a small crank you bring a series of lenses into position. You are looking at a card, on which some words are printed, as, "if you can read this you do not require spectacles." If writing can only be read with certain lenses, then the No. of spectacle required is also read, and on satisfying oneself that these lenses suit, on withdrawing foot a box is set free, in which are order forms, on which No. can be entered. Convex and concave glasses are used for testing in this ingenious manner. The company offer to supply spectacles to order at 4*s.* 6*d.* Medical men interested can inspect the apparatus, by appointment, with Messrs. Woodhouse, Rawson & Co., Hammersmith, London.

THE COLLECTIVE INVESTIGATION COMMITTEE.

As is well known, we opposed this expensive organisation, and we pointed out in the *British Medical Journal* the fallacies that we believed were connected with it. Our opposition was regarded as a personal attack on the eminent organisers of the idea. At Copenhagen, when we met the late Dr. Mahomet, his first words were: "I do not know whether I ought to speak to you." "Why?" we asked. "Because you have so opposed this committee." "But," we rejoined, "we have not opposed you; we have dealt with principles, not men." Dr. Mahomet was too broad-minded to act as some little men would have acted, and our relationship with him is now a pleasant recollection. The editor of the *British Medical Journal*, in his "Topics of the Day," July 15th, sings the *requiem* over this organisation: "Its success has been so dubious," he says, "that after a brief period of existence its animation has, I regret to see, been suspended. I pointed out its sources of inherent weakness, [*we* do not remember reading any published paper of Mr. Hart's to this effect] and the improbability that it could fulfil the large expectations formed of it here, and which for a moment attracted the imagination of other associations, and of the International Medical Congress. It was born with great *eclat*, baptised with many benedictions, welcomed with loud soundings of trumpet at Copenhagen; but neither energy, liberal subsidy, nor the devotion of some of the finest intellects in Europe could keep it alive."

It is useless to beat a dead horse. *Fuit* may now be written across its history, but the lessons are not to be lost. We need hardly point out what these are. In our opposition we disregarded the weight of authority, and considered the measure on its merits. We simply acted as Huxley lays down in his "Lay Sermons," p. 18: "We refuse to acknowledge authority as such. The conditions of resistance to authority are clear. Scepticism, where natural knowledge is concerned, is the highest of duties; blind faith, the one unpardonable sin . . . the most ardent votary of science holds his firmest convictions, not because the men he most venerates holds them. The man of science has learned to believe in justification, not by faith, but by verification," We regret to say that this spirit does not enter sufficiently into some medical minds. To oppose a new theory or new departure in therapeutics is, with some, tantamount to opposing the man; if the man be good (as if there were any merit in this, for all men should be good) the sin of opposition is all the greater. Our general views on professional subjects are freely expressed; we do not attack a man, but a system; if the system be assailable, *tant pis* for the system. Nothing in science now-a-days can live by authority: it may be bolstered up for a time on the shoulders of eminent names, but time comes in, and as with the Collective Investigation Committee, the inherent weakness of the system kills it.

NANTWICH AS A HEALTH RESORT.

Nantwich is a small town of great antiquity, situated in one of the most fertile parts of Cheshire, and being only ten minutes from the important railway centre of Crewe, on the London and North Western Railway, is easy of access to almost any part of the United Kingdom. The health of the town is exceptionally good, zymotic and tubercular diseases comparatively rare, and no death from typhoid fever has been recorded for several years. Mr. Fox, the Medical Officer of Health for Mid-Cheshire, speaks strongly of these facts in his reports, and also of the excellent sanitary arrangements. The great feature of Nantwich at the present time is the existence of the old brine pit, with a shaft sixty feet deep, from which brine is pumped and used for the hot salt baths. The analysis of the brine made by Dr. Frankland, D.C.L., F.R.S., proves the Nantwich baths to be the strongest saline baths in the world. The climate of Nantwich is equable, mild, and dry; heavy falls of snow are rare, and fogs are also infrequent. The effects of the brine baths are tonic and stimulant. Under their influence, circulation is increased, nutrition improved, and nervous tone is invigorated; while in regard to a certain class of nervous disorders and diseases of a gouty and rheumatic nature, they exercise a marvellous curative influence. We have heard of some wonderful cures of sciatica, rheumatism, and gout; and if English sufferers from these painful disorders would be content to try English brine baths, instead of rushing off to continental baths, leaving their friends and home comforts behind them, much inconvenience and fatigue would be avoided. The baths were erected five years ago by three resident gentlemen, more with a desire to relieve suffering humanity than with the idea of making money. The brine is so strong that in the swimming bath, the swimmer can easily walk in the water without the chance of sinking; and

in the hot baths it is necessary to strap the patients down, otherwise they float on the top. Besides the swimming and hot baths, there are vapour, douche, and needle baths.

Many sufferers have been relieved by the Nantwich waters after trying unsuccessfully, both at home and abroad, better known and more fashionable baths. Unfortunately, the Nantwich baths are little advertised, and consequently little known. In the present age, when everything is so extensively advertised, we are much struck by this fact; but we understand that the promoters have such full confidence in the efficacy of their wonderful waters, that they believe time will do for them—certainly, though perhaps more slowly—what advertising has done for the better known health resorts, both of this country and the continent. These baths are given much stronger than brine baths in other places, on account of the brine being heated with steam, and not by the addition of hot water, as is done elsewhere. Any information about the Nantwich baths, and copies of testimonials, can easily be obtained from the obliging secretary, Mr. H. Claud Lisle, solicitor, Nantwich. Dr. Munro is the consulting physician. Nantwich has one great advantage over most country towns: it has a splendid church, dedicated to St. Mary. This is a magnificent specimen of work of the fourteenth century, of a cruciform building of red sandstone, with a very fine octagon tower. The ornamentation of the interior is simple, but the lines and proportions are singularly pure and beautiful. The carved stone pulpit is one of the most remarkable in the country, and the stone groining of the chancel roof is most graceful. Nantwich is in the centre of one of the finest hunting counties in England, and within driving distance of the meets of four celebrated packs of hounds. The Empress of Austria selected this neighbourhood for hunting during her last two visits to England. Some of the old buildings in Nantwich are most quaint and picturesque, and are beautiful specimens of the Cheshire curious style of architecture. There are many places of interest in the neighbourhood, including Combermere Abbey, Peckforton Castle, Beeston Castle, Cholmondelly Castle, city of Chester, and Eaton Hall. A handsome little free library was founded in 1888, which contains many excellent books.

PROPOSED RESOLUTIONS.

The following will be proposed at the August meeting of the British Medical Association: "Recognising the fact that there is an abuse of the *Out-patient Department* of your Medical Charities, this meeting of the British Medical Association resolves—

"1. That medical practitioners and the managers of our medical charities in the various towns and cities, meet together and decide who are eligible for *out-patient* medical aid. This meeting suggests that the following average limit be adopted: When a man and wife make 25*s.* per week and over, or a single person 20*s.* per week and over, that these shall be *ineligible* for *out-patient treatment* at the medical charities—except in cases of accident—and that those earning a similar rate of wage be ineligible for 'home visits'—*i.e.*, visits paid by the staff of the medical charities to sick persons at the patient's home. Further, that either the Manchester system of checking abuse, or that used at the London and St. Bartholomew Hospitals be put into force, but that preference be given to the plan used in Manchester.

"2. In order that those who shall be excluded from the *out-patient* department of our medical charities (by the working of the previous resolution) may have the means of obtaining *immediate* and efficient medical, surgical, and dental treatment, and medicines. This meeting resolves, that a Public Medical Service—such as that suggested in the *Journal* of June 22nd, 1889—be formed, and that this Service embrace those wage earners who are making *under 45s. per week, per family*, and single persons under 30*s.* per week. And that the medical practitioners, dental surgeons, chemists, and hospital managers, are requested to bring about this hospital reform, and establish a Public Medical Service with as little delay as possible.

"3. That having secured hospital co-operation, and having established a Public Medical Service, the members of this Association appoint a committee, composed of two representatives elected by each branch, and that this committee draw up a series of rules for the formation and working of a provident system, whereby wage earners receiving up to 45*s.* *per week, per family*, and single persons 30*s.* per week, may, by making periodic payments during health and sickness, provide themselves, their wives, and children, with efficient medical and surgical treatment, and medicines.

"4. That the principle of a 'wage limit' be adopted, and worked by friendly societies, tontines, and sick insurance companies; or that a 'sliding scale' of payments be made to their medical practitioners, so that the present abuses may be rectified. This scale of payments to be drawn up by the committee constituted as by resolution three. This meeting suggests that the *minimum* medical fee paid by such sick clubs shall be 6*s.* per annum per member: that the person proposed for membership pay a fee of 3*s.* 6*d.* for the medical examination (whether admitted to membership or not) to the practitioner who so examines: that the sum of 1*s.* be paid to the practitioner by the person who obtains it; and that the sum of 8*d.* be paid for each prescription dispensed. This meeting earnestly requests the various authorities of friendly societies, tontines, and sick insurance companies to make provision for surgical and dental treatment, and to draw up a scale of fees for the same, so that they may not be depending on the medical charities for relief.

"5. That this meeting, recognising the fact that there are a great number of beds in the Poor-law infirmaries (there being no less than 12,000 in twenty-five metropolitan Poor-law infirmaries), and many in the various fever hospitals, at present unused for the clinical teaching of students; and giving due weight to the statement made in the Metropolitan Asylums Board Report of 1889 (p. 18), that 'your committee cannot fail to observe the large proportion of mistakes which are made in the diagnoses of small-pox and fever,

desire to express their regret that the Poor-law infirmaries and fever hospitals are not open for the clinical instruction of medical students, and hope that the various authorities will direct their attention to the removal of the present restrictions, so that the educational standard may be improved—it being essential to the health of cities and towns that medical practitioners may be able to recognise fever cases at the earliest possible period.'

"6. That the Council and *Journal* of the Association help in every legitimate way to bring the above resolutions to a successful issue."

MALCOLM MORRIS INDEMNITY FUND.

It is felt by many of Mr. Morris's friends that he should not be allowed to bear the heavy costs (£462) of the recent trial, in addition to the months of anxiety and worry he has been compelled to undergo. By his courage and promptitude Mr. Morris has done a service both to the profession and to the public which requires a more solid recognition than a simple expression of sympathy.

The following subscriptions have been promised, and those who desire to contribute are requested to communicate, without delay, with Mr. G. P. Field, 34, Wimpole-street, London, W., or Dr. Sidney Phillips, 21, Upper Berkeley-street, W.

New Remedies.

Ulexine, the active principle extracted by Mr. A. W. Gerrard from the common furze (*Ulex europæus*), has been subjected to numerous experiments by various therapeutists, with a view to determine its medicinal properties. According to Dr. J. Rose Bradford, it is a nerve and muscle poison, as well as a respiratory poison, increasing arterial tension and producing diuresis. Dr. E. H. Fenwick states that although it is a powerful diuretic, it must be employed with caution in stricture, one tenth of a grain having caused temporary suppression of urine, vomiting, and fever. M. Pinet, in the *Archives de Physiologie*, expresses his belief, as the result of experiments, that ulexine acts as an antidote to strychnine.

Menthol.—Attention has lately been directed to the internal use of menthol as an anæsthetic. According to Dana, its effect when given internally in doses of five to twenty grains, is to stimulate the cardiac action without increasing its rapidity, and to raise the arterial blood pressure. As an anæsthetic or anodyne in headache and neuralgia, Dana recommends it in preference to antipyrin for weakly and anæmic individuals. In migraine and supra-orbital neuralgia it has been found especially useful. In the opinion of the writer it would probably be well worthy of trial in cholera, as it unquestionably acts as an antiseptic and anæsthetic in the diarrhœa of abdominal catarrh, when the bile duct is obstructed, and bile, the natural antiseptic, is absent or nearly so from the fæces. Menthol is easily taken in the crystalline form if washed down at once with water. *Safrol* in doses of twenty drops is stated to possess similar properties in headache and sciatica.

Sodium dithiosalicylate has now been prepared in two forms, and has been tested therapeutically at Frankfort by Dr. Linderborn. The first form was given in doses of 0.2 gramme, morning and evening, and when stronger doses were required, it was given in the evening every hour for three or four doses. It has been tried chiefly in articular and gonorrhœal rheumatism. In the milder cases the pain and fever were overcome in two days, and in the more severe in six days at the most, when the swelling of the joints disappeared. The medicine acts promptly as an antipyretic, except when administered to phthisical patients. It also possesses a powerful antiseptic action. The second form of the salt has a more powerful action in smaller doses, and does not subsequently produce any objectionable symptoms. It is a gray white powder, very hygroscopic, and easily soluble without residue in water, the solution giving with ferric chloride a faint purple colour. From an acid solution of the salt, the acid separates in yellow resinous drops, that are nearly soluble in water.

Santonoxim, a new compound of santonin, has been recommended by M. Coppola as a substitute for santonin. He believes that the poisonous symptoms sometimes following the administration of santonin are due to an excess of lactic acid in the intestines, by which the solution and consequent absorption of the santonin are favoured, the excess of lactic acid being due to an intestinal catarrh produced by the worm. Santonin, being less readily absorbed and non-toxic, is found to be equally active when administered in double or triple doses. Santonoxim was obtained by Professor Cannizaro in 1885, by the action of the hydroxylamine upon santonin in an alkaline liquid. Its formula is C_{15} H_{18} O_2 NOH.

Naphthol has not perhaps been received so favourably as would otherwise have been the case, in consequence of the difficulty in dispensing it. It has recently been found, however, that naphthol can be dissolved in considerable quantity by alcohol, and that for external application a concentrated solution of this kind can be used. For weaker solutions, the alcoholic one is diluted with an aqueous solution of soap, the alkaline and viscous character of the liquid augmenting the solubility and facilitating the miscibility of the naphthol in the menstruum.

Thiocamf, a new disinfectant, has been highly recommended by Dr. Emerson Reynolds. The basis of it is a liquid formed when sulphur dioxide and camphor are brought in contact. It seems that although sulphurous acid gas requires a pressure of at least two atmospheres for its liquefaction, contact with camphor effects the liquefaction at once without any pressure. The liquid can be kept in bottles without decomposition, and without pressure at ordinary temperatures; but the exposure of it to the air in a thin layer determines the regular evolution of relatively enormous volumes of sulphuric acid gas. Other bactericides are said to be added to this mixture, but the nature of them is kept secret, as the disinfectant is to become the subject of a patent.

Hydracetin, a new antipyretic, is stated to resemble pyrodin, but to be a pure acetyl-phenyl-hydrazin; whereas pyrodin represented only one-fourth of the activity of that compound. It does not appear, however, to be any safer than pyrodin, since it is expressly stated that its internal administration must be watched, and must not be continuous. The doses given in rheumatism of the joints range from five to twenty centigrammes in the day, and only in rare cases to thirty centigrammes. It has also been used with success in psoriasis in the form of a 10 p.c. ointment. Hydracetin occurs as a white, almost tasteless and odourless powder, soluble in about fifty parts of water, and also in alcohol. It has a powerful reducing action, which is considered by Dr. Guttmann to stand in relation to its antipyretic and anodyne properties. It readily reduces alkaline cupric solution in the cold, and precipitates metallic silver from an alkaline solution of silver; it throws down from a mixture of a solution of potassium ferricyanide and dilute solution of ferric chloride an immediate precipitate of Berlin blue, converts mercuric into mercurous salts rapidly on warming, deodorises solution of potassium permanganate, and reduces chloride of platinum to metallic platinum.

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. Kesteven, M.D.

A Cerebral Abscess healed. Von Bergman (*Centralblatt für Chirurgie*, June 1st, 1889).—A man, æt. twenty-five years, had suffered since the age of fourteen from purulent discharge from the right ear. From time to time he had experienced pain in the same part. From his earliest years he had suffered also from giddiness and constant headache on the right side. He was in a great degree apathetic. There was no loss of motor power. The left arm and leg were moved more easily and quickly than the right, which had slightly less cutaneous sensibility. The muscles of the right side of the face were somewhat paretic. The wall of the meatus was covered with granulations, and pressure caused the flow of pus. On one small circumscribed spot behind the ear percussion, gave rise to severe pain. The sense of hearing was diminished, so that the patient was deaf on that side at the distance of three paces. From these symptoms abscess was diagnosed in the brain substance of the temporal lobe. This was confirmed by trephining at the lower angle of the right parietal bone, which gave exit to green fœtid pus. The wound was dressed antiseptically, and healed in six weeks' time.

On the Proportion of Water contained in the Blood (*Le Progrès Médical*, June 8th, 1889).—MM. Grehant and Quinquand have determined an increase in the proportion of water in the blood after hæmorrhage, or after the ingestion of water into the stomach. They also find that the venous blood contains less water than arterial blood, which they explain by the passage of water from the veins to the lymphatics.

Sugar of Milk a Diuretic in Diseases of the Heart. M. Germain Sée (*L'Union Médicale*, June 15th, 1889).—M. Sée, from his investigations, has arrived at the conclusion that sugar of milk acts directly upon the renal epithelium, which it stimulates into action without augmentation of blood-pressure. Lactose acts similarly to caffeine without producing cerebral disturbance. The diuretic action of milk M. Sée finds to be due to the sugar of milk, which he regards as one of the most powerful and surest diuretics. Its action had been carefully observed and recorded in twenty-five patients. One hundred grammes of sugar of milk will produce a more profuse diuresis than four or five litres of milk. Its action is certain in cardiac affections, but is not so in renal disease. As a medicine it is borne well. After

eight or ten days its use should be suspended for a few days and then resumed. It has this advantage, that it does not preclude any other diet.

On the Function of the Coccyx in Parturition. By H. Fry (*Centralblatt für Chirurgie*, No. 22, quotes from *American Journal of Obstetrics*, 1888).—Dr. Fry points out that the coccyx has a share in the function of parturition. It is, he urges, contrary to the laws of nature that this bone should be placed at the outlet of the pelvis except for some useful purpose. This function, Dr. Fry holds, is to control the sudden or too-rapid extrusion of the forehead, and to guide the occiput under the symphisis pubis. The finger passed into the rectum will be felt to be pressed against the coccyx at each pain, and pressure will then occur upon the occiput at the symphisis.

Heredity in Myopia (*L'Union Médicale*, June 13th, 1889).—M. Motais, of Angers, submits the following propositions from the examination of 330 young persons. Heredity existed in 216 out of the 330 families—65 per cent. Hereditary myopia is to be distinguished from the acquired defect by its previous appearance and rapid development, and its more frequent and extensive complications. Myopia is transmitted, generally, from father to daughter, at the rate of 86 per cent.; and from mother to son, at 79 per cent. The conditions that favour myopia are unhealthy hygiene and deformity of the orbital arch (in 16 per cent.).

Case of Acute Cocaine Poisoning (*Centralblatt für Chirurgie*, June 1st, 1889).—A dentist, for the extraction of a tooth from a vigorous but somewhat chlorotic girl, nineteen years of age, had injected into the gum, in two portions, 0.1125 gr. of cocaine. After the second injection the patient suddenly became pale, and fell into convulsion. When seen by Dr. Hanel she was quite unconscious, slightly cyanosed, and suffering clonic spasms, which continued five hours. The pupils were widely dilated, and did not reach to light. The pulse, at first could not be counted, came down to 174; the breathing 44. After the cramps subsided the patient remained unconscious for two hours. On being roused she could not look about, had intense photophobia, diminished sensibility of the surface, anæsthesia of the mouth and interior of the nostrils, thirst, retention of urine for twenty-four hours, sleeplessness during the next day, severe cardialgia, and entire loss of appetite. The symptoms disappeared gradually in the course of two or three days. Nitrite of amyl, the application of cold to the head, and large doses of opium had no effect.

A Case of Lupus Miliaris. Dr. During (*Centralblatt für Chirurgie*, June 1st, 1889).—This eruption, also known by the name of acne-lupus, appeared on the cheeks and temples of a young woman, and was at first regarded as acne. It then became of a reddish-brown colour, and partly transparent. The treatment for acne had no effect. Creasote and salicylic acid were then applied; the pimples were destroyed and cicatrices were left. From the peculiar aspect of the eruption Dr. During considered it to be the "disseminated follicular lupus" of Fox, and applied to the case the epithet "miliary lupus."

Hydroxylamin, a New Remedy in Skin Disease. Eichkoff (*Centralblatt für Chirurgie*, June 1st).—Dr. Eichkoff has met with satisfactory results from the use of the hydrochlorate of hydroxylamin, in a one-per-cent. solution of equal parts of glycerine and spirit. The seat of disease is first washed with soap, and then painted from three to five times a day with the solution. Five cases of lupus were rapidly cured under this treatment, and favourable results are reported of herpes tonsurans and sykosis. Dr. Eichkoff warns against the use of a stronger solution than one per cent.

The Predisposing Causes of Hysteria. By. M. Georges Guinon, Paris (*Le Progrès Médical*, 25th May, 1889).—The predisposing affections enumerated are cited from the researches of M. Charcot, thus: *moral emotions*, hypnotic experiments, nervous shock, terrestrial tremors, lightning storms; *general and infectious diseases*, such as typhoid fever, pneumonia, scarlatina, acute rheumatism, diabetes mellitus, paludism, syphilis; *morbid conditions characterized by debilitating effects*, such as hæmorrhages, physical or mental overwork, Onanism and excess of venery, anæmia, and chlorosis; *intoxication*, whether chronic (such as lead, mercury, alcohol, sulphuret of carbon) or acute (as from anæsthetics in surgical operations); *disorders of the sexual organs; some diseases of the nervous system—e.g.*, sclerose en plagues, tabes dorsalis, progressive myopathy, gradual compression of the spinal cord, as in Potts' disease.

Statistical Note upon the Share taken by Consanguinity in the Etiology of Epilepsy, Hysteria, Idiocy, and Imbecility. By Bourneville and Courbarien (*Le Progrès Médical*, June 8th).—In the following table the authors give the result of their scrutiny of 926 cases taken in the Bicêtre and La Salpêtrière. In all cases the fact of relationship between the parents has been noted.

II.—SELECTIONS FROM CONTINENTAL MEDICAL JOURNALS.

By G. F. Cadogan-Masterman, M.D.

Los estados Tifodicas por Fatiga. By Dr. Eloy (*Revista de Ciencias Médicas*).—What is fatigue? Where does it begin, and how does it end? Questions apparently simple enough, but not very easy to resolve. We all, happily, know what it is; we have all felt or feel its effects, and there are many people who are always saying, "Oh, how tired I am!" Like Mariana—

"She said, 'I am aweary, aweary,
I would that I were dead!'"

Yet they cannot describe what they really feel. Amongst scientific men there is little accord, when they notice the subject, as to the cause of this fatigue, which is evidently not due to mere or continuous work, for our heart and lungs never tire.

Littré defines fatigue as a painful sensation due to excessive or too prolonged toil; Robin, in the article "Fatigue," in Nysten's Dictionary as "An exaggerated activity in any part of the body, external or internal, provided with feeling which determines a certain condition in those parts, and which is transmitted to the nerve centres, and felt there; this perception is termed fatigue, or the sense of being tired." Sensation of fatigue! this may be a definition, but it does not tell us what fatigue itself really is, no more than the pain from a blow explains how that blow was given. Many other writers have said the same thing in other words; they have never gone beyond the sensation to find the cause.

Now fatigue is not a perception, a sensation or a mode of feeling, but a profound and functional disorder of those anatomical elements the activity of which has been excessive, and in which reparation has been deferred or rendered impossible for a time. In other words, fatigue is the consequence of perturbations which have interfered with nutritive repair, a pathologic condition of muscular starving, and of which the remedy is rest and food. And in proof we must turn to clinical observation and animal chemistry.

It has been long known that muscular movement produces certain mechanical results, and is attended with the evolution of heat; also that it gives rise *inter alia* to the formation of creatin, creatinine, and lactic acid; residual substances which, according to the experiments of Keim and Prayer, are provocation of sleep, mental disturbance, and even paralysis. Or, as a generalisation, that living cells—as a result of their own activity—throw into the circulation a number of poisonous substances, leucomaines, cadaverines, the degradate of their own constituents.

Long before this had been made out physiology had attributed to the skin, to the liver, and the kidneys most important emunctory powers, and taught that perspiration, the urine, and the bile carried away from the body the residual results of its own life. And that if these organs did not so purify the blood, and the bowels carry away the unused food, uræmia, colœmia, estercorœmia, creatinœmia would happen as evidence of an auto-intoxication of the system.

Now exactly in the same way as these poisonous bodies accumulate when the organs—whose duty it is to get rid of them—fail or cease to act, so, during excessive toil their abnormal production exceeding the capability of the circulating system to carry them away, we have *ponogesia* (*πόνος fatigue*); and the pain and exhaustion are its symptoms.

And this is not quite hypothetical: Bouchard determined experimentally the co-efficient of the toxicity of the urine of a person suffering from excessive fatigue. In a lecture on "Auto-intoxication" (April 14, 1886) he showed that this was twelve cub. centimetres to each kilogramme of the weight of the animal experimented upon; whilst the urine of the same man after rest had to be injected to the amount of forty-five cub. centimetres to produce the same effect. That is, the urine of a subject exhausted by fatigue is nearly four times as poisonously active as that of ordinary conditions.

Some allowance should, of course, be made for the loss of water during hard work by the skin and the resulting concentration of the urine, and the difference is mainly due to the much larger quantity of urea excreted during excessive muscular toil; but it would not be theorising too much to say that, owing to imperfect oxidation of the nitrogenous tissues, other bodies of more poisonous activity may be thrown off, and appear in the urine. As in other abnormal conditions, there are various grades of fatigue: simple lassitude, prostration, exhaustion—attended sometimes with a raised, but usually with reduced temperature. We may call it a typhoid state without fever. There is muscular prostration, dried lips and rough, parched tongue, stupor, sometimes delirium, fœtid breath, loss of appetite, and often marked anæsthesia of skin, whilst the whole body internally seems a bag of aches and pains. And we see examples on every side. Now it is a young soldier who has recently joined his regiment; a dust-laden wayfarer; a servant, newly transported from her village home to a crowded city; an author, writing against time; a young husband, who thinks a lifetime all too short for hymeneal enjoyment. The cause matters little; the result is ever the same—the exhausting march, overstrained brain, prolonged vigils, venereal excess, all lead to the same typhoid state, and made worse by concomitant privations, sufferings moral and physical, nostalgia, or mere weariness of life—all tending in the same direction, or rather, let us say, all springing from the same point: excess of work, with deficiency of cell nutrition; and this has no necessary connection with an empty purse or stomach. It is interesting to notice how much the facial expression of a person worn out with fatigue resembles that of typhoid. And if, as is so often the resource of the lower class, alcohol is taken in place of the natural remedy of rest, we have the additional symptoms of a furred tongue, intense headache, injected eyeballs, complete anorexia, insatiable thirst, with abdominal tenderness and meteorism, which may well make the diagnosis difficult enough if we come upon some homeless outcast, lying in deep stupor by the scarcely more dusty roadside—a mere inarticulate heap of sordid wretchedness. Happily, however, after a warm bath and a few hours' rest in bed, we find our patient resolving his own case into its simplest elements—an auto-intoxication, perhaps *plus* alcoholic, and typhoid without fever.

III.—NOTES FROM FRENCH JOURNALS.

By H. R. Hatherly, M.R.C.S.

Recent Views on Diabetes (*Le Progrès Médical*).—Dr. Dujardin-Beaumetz makes a distinction between glycosuria, which is only a symptom, and diabetes, which is a disease. Of the latter, there are three forms: one form slight and benign, another slow and moderate, and a third grave. The prognosis should not be based on the quantity of sugar which is ascertained, but by the results of diet and *regimen* The *regimen* should be very strict. Dr. Beaumetz prohibits milk, allows 100 grammes of boiled potatoes with each meal, prohibits brown bread, fatty food and pork meats; beverages are sweetened with saccharine, the maximum daily dose to be ten centigrammes, tea and coffee are substituted for alcohols. To this regimen he adds as medicines: bromide of potassium, exalgine, or antipyrin. Muscular exercises are of very great value.

Dr. Germain Sée asserts that normal urine contains sugar. Phenylhydrazin, a new and valuable reagent, reveals 33 milligrammes in 100 grammes of urine in 17 per cent. of healthy individuals. These individuals are not diabetic if, after partaking of 160 grammes of white bread, the quantity of sugar eliminated does not vary. In other words, 250 grammes of cane sugar, or 200 grammes of sugar of milk, must be swallowed, in order that sugar may be eliminated by the urine. Amongst the diabetic, on the other hand, the smallest quantity of these substances is detected in the urine, and increases the existing pathological amount. Glucose is also formed normally in the economy, either by the modification of amylo-saccharine substances in food, or by the transformation of glycogen, or at the expense of the albuminates from without or within. There may, therefore, be a normal glycosuria by simple exaggeration of the ordinary phenomena of life, but on condition that the sugar in the urine is introduced, and that the glycogen of the liver and muscular tissue has not undergone any modification. There is but one step from normal glycosuria to permanent diabetes. This step is taken when the circulation of the liver is altered by the vaso-motor system of this organ, under the influence of irritation of the spinal cord (Claude Bernard), or of other nervous centres. This increased activity exaggerates the genesis of glycogen, and the rapid and excessive transformation of it into sugar. Diabetes is always, in consequence, the result of hyper-glycosuria, which is in the majority of cases of nervous origin. The excessive quantity of sugar formed acts by diuresis, and drains away the pre-existing sugar. The nervous system must be treated, and thereby benefit may be derived.

Erysipelas and Circumcision (*L'Union Médical*).—A Jewish mother was confined on the 27th of April, 1889, of a healthy boy; at the same time the grandfather (an octogenarian) was suffering from facial erysipelas, with large phlyctenœ. The grandfather made a rapid recovery, and notwithstanding slight desquamation, was able to go out on the sixth day, and had communication with the child. Circumcision was performed on the 4th of May, and all went well; but as there was still slight desquamation on the face of the old man, he was not permitted to touch the child. The operator prepared the child, which showed no signs of uneasiness. He observed in the right groin two or three blisters, which were torn whilst washing the genitals. He attached no importance to them, and did not connect them with the grandfather's erysipelas. The operation was performed in the orthodox Jewish manner, and bleeding was slight. The wound was sucked three times, the mouth being filled with wine. The child remained well during the day, but at night was restless, and had little desire for the breast. The following day the wound was nearly healed, and the child seemed in perfect health. The third day the child was restless, hoarse from crying, and very feverish. The wound had entirely healed; the penis and scrotum were normal; but the thighs and legs were covered with broken phlyctenœ, with portions of epidermis hanging loose. There was no longer doubt that the child had erysipelas, commencing in the early vesicles, and due to infection from the grandfather. The manner of contagion was clear, otherwise it might have been alleged that it was caused by the suction. The erysipelas spread little by little over the whole body, from the soles of the feet to the crown of the head, the genitals alone escaping. The child did not entirely recover until the 24th of May. The following facts may be noted in this case:

1. A child six or seven days old may be infected by erpsipelas during desquamation, even if the skin presents no breach of continuity.

2. The wound of operation, made according to the traditional Jewish method, was not influenced in the slightest degree by the erysipelas.

3. The parts operated upon and sucked alone escaped a disease which attacked every other part of the body.

It seems probable that the suction and the bleeding is really a safeguard from a complication which might prove very dangerous.

Prophylaxis of Hydrophobia after Dog-bites (*L'Union Médicale*).—From the 1st of May, 1888, to the 1st of May, 1889, 1,673 patients have been treated in the Pasteur Institute, all bitten either by mad dogs, or by dogs strongly suspected of madness. Of these, 1,487 patients were French, and 186 of other nationalities. Out of the 1,673 persons, 118 were bitten on the head or face; six persons, of whom four were bitten on the head and two on the limbs, were attacked by hydrophobia during the treatment; four others were attacked within fifteen days of the conclusion of treatment; three persons bitten on the head died after the completion of treatment, so that the method failed only three times in 1,673 cases, a mortality of one in 554. If the ten cases whose deaths had been previously referred to were added to these three (which would be illogical), there would then be thirteen deaths out of 1673 cases, or a mortality of one in 128.

Treatment of Heart and Lung Disease by Inhalations of Chloroform (*L'Union Médicale*).—Professor Rosenbach recommends strongly inhalations of chloroform in all those diseases of the heart and lungs in which other narcotics, such as morphia or chloral, act too slowly, and are followed by unpleasant secondary results. He proceeds as follows: Some lint is placed in a funnel, on which is placed from five to fifteen grammes of chloroform. The patient breathes the vapour slowly, holding the chloroform at a little distance from the mouth and nose. As the chloroform is diluted with air, no danger need be apprehended. At the commencement, the patient experiences an unpleasant sensation in the pharynx, which speedily passes off, and the patient makes deep inspirations, which afford a sense of relief, and often induces sleep. Professor Rosenbach has never observed mischievous secondary phenomena to follow this treatment. Inhalations of chloroform are indicated in all cases of attacks of cardiac or pulmonary dyspnœa, but more especially in emphysema, cardiac asthma, and disease of the heart. Good results have also been obtained from its administration during the frequent attacks of cough in the phthisical. Patients who before inhalations had suffered from absolute

insomnia, slept quietly enough after one or two applications during the night. Satisfactory results are obtained in hiccough, and in attacks of intense cardialgia, although in these cases morphia is preferable. Attacks of pulmonary œdema have been cut short. He also advises that tuberculous ulceration of the larynx should be mopped with an aqueous solution of chloroform. The improvement which follows may be explained, partly by its analgesic action, and partly by its parasiticide properties.

Dangers of Sulphonal (*L'Union Médicale*).—After the administration of one grain five centigrammes of sulphonal, a woman, æt. forty-five years, experienced the beneficial effects of the remedy during a period of four days; but as she persisted in its use to relieve habitual insomnia, she was attacked with vertigo, marked gastric symptoms, paralyses, and psychical and cardiac disorders. It was only after four weeks' absolute suspension of the employment of this sorry remedy that she was able to walk a few steps, and even a week later she walked unsteadily. A man, æt. fifty-one, suffering from melancholia, under the influence of two grammes of sulphonal suffered from nocturnal hallucinations. The following day he had vertigo, and vomited several times, and was unable to leave his couch. After a lapse of several days the remedy was again tried, but with the same want of success, and the same symptoms. A nervous lady, æt. thirty-two, who suffered from habitual insomnia, after a single dose of two grammes, remained four days in a somnolent condition, semi-conscious, and feeling continual vertigo. She had no gastric symptoms. Against these instances of intolerance of sulphonal in moderate doses may be cited the case of the courageous Berlin gentleman who, having a strong desire to sleep soundly, took the formidable dose of thirty grammes. He had time to quit the public house where he performed the experiment, and to return home. He had an uninterrupted sleep from Sunday night until the following Saturday morning. He woke up, and slept until Wednesday at one o'clock, when he again awoke. He had a splendid appetite.

Hydrophobia at Toulouse (*Gazette de Hopitaux de Toulouse*).—For some time past canine madness has been prevalent at Toulouse. Two children, recently bitten, have just been sent to the Pasteur Institute. Since then a number of dogs in the town have been ascertained to be mad. The mayor has drawn up a regulation, which concludes as follows: "The public are warned that after the 1st of July all stray dogs found wandering in the streets, either by night or day, will be poisoned."

Deaths from Hydrophobia in the Pasteur Institute (*Le Progrès Médical*).—A man named Moons, of Antwerp, was bitten on March 2nd, 1889, by a dog certified as mad by Mr. Dell, a veterinary surgeon, who examined the dog whilst living, and also made its autopsy. Moons was bitten on the right knee in four places, which did not bleed, although the trousers were torn. He was also bitten on the right side of the chin, at the level of the inferior margin of the maxillary bone; on the lower lip near the left commissure; and in two places on the left cheek. All the bites on the face bled; they were not cauterised, and only dressed by a surgeon after a lapse of four days. Moons was treated from March 7th to April 2nd, and died of hydrophobia on May 17th, 1889.

Mdme. Maillot, æt. eighty-six, of Contasiora (Côtes du Nord), was bitten on April 27th, 1889, by a dog ascertained by M. Le Berre, a veterinary surgeon of Lannion, after a *post-mortem* examination, to be suffering from rabies. A dog which had been inoculated from it on May 3rd had rabies on May 15th. Mdme. Maillot was bitten on the right leg in the anterior portion of the lower third; there were two deep bites which bled profusely. The bites were cauterised with alkali eleven hours after they were inflicted. Mdme. Maillot was treated from the 3rd to the 17th of May. She was seized with paralytic hydrophobia on May 30th, and died on June 2nd, 1889.

Prohibition of Public Exhibitions of Hypnotism.—The Departamental Council of Public Hygiene and Health having expressed a wish that exhibitions of hypnotism should be prohibited on account of the numerous mishaps they have caused, the Rector of the Academy at Poitiers has forbidden all demonstrations of the kind in the schools placed under his supervision. The Mayor of Marseilles has also forbidden public exhibitions of hypnotism in public schools. These are measures which cannot be too highly commended.

The Earliest Inoculations of Variola in France (*Le Progrès Médical*).—The first inoculation of variola made in France was in 1774 by Lassone on the royal family; but a more thorough trial was made in July, 1799, when Vergez, jun., inoculated twenty-two pupils at the "Prytanèe," then the College Louis le Grand. Vaccination was discovered in 1796, but it was not until 1800 that Woodville introduced it into France.

Society for the Protection of Victims to Medical Duty (*Le Progrès Médical*).—This association is now definitely constituted, and has already made a grant of 500 francs to assist Madame Merandon, the widow of a medical man who contracted diphtheria whilst attending a poor child, and who is in distressed circumstances. The treasurer of the society has been instructed to pay the debts of Madame Merandon, to purchase furniture for her, and to provide for her most pressing wants. The society will endeavour to obtain for her employment suitable to her age, health, and aptitude.

IV.—NOTES FROM RUSSIAN, POLISH, AND SWISS JOURNALS.

By Valerius Idelson, M.D., Berne.

On the Influence Produced on the Secretion of Saliva by Stimulation of the Cerebral Cortex.—Professors Vladimïr M. Bekhtereff and Nikolai A. Mislavsky, of Kazan, describe (sep. reprint from the *Meditzinskoïe Obozreniïe*, 1888, No. 13, p. 52) their experiments on curarised dogs, undertaken with the object to elucidate the action of the cerebral cortex in regard to the secretion of saliva. Having inserted cannules into the Whartonian and Stenonian ducts, the authors freely opened the animal's skull, and stimulated successively various areas of the cortical surface by means of two needle-shaped electrodes supplying a weak current from the bobbin of Du Bois Raymond's sledge-apparatus. The effects were appreciated by determining the amount of the saliva flowing from the cannules. The experiments have shown that: 1. As regards the *submaxillary gland*, the most intense secretory effects are obtained from irritation of that portion of the fourth primary gyrus which is situated above, and in front of, the Sylvian sulcus. Even very weak currents, applied to the area, continue to excite the submaxillary secretion. 2. The latter is further induced by stimulating—though by somewhat stronger currents—(*a*) the whole anterior portion of the sigmoid gyrus—in front of the *sulcus cruciatus;* (*b*) the outer surface of the posterior portion of the same gyrus; and (*c*) the anterior parts of the second and third primary gyri. 3. As regards the *parotid gland*, the secretion is induced solely by stimulation of the said division of the fourth primary gyrus (*vide sub* 1.) 4. Stimulation of the frontal lobe does not show any influence upon the secretion of saliva. 5. Stimulation of the parietal, occipital, and temporal regions of the cortex, as a rule, gives negative results. Now and then, however, a strong faradisation of the areas just named gives rise to some increase in the submaxillary secretion. 6. The secretion on the side of stimulation is mostly more active than on the opposite one. 7. The submaxillary saliva, obtained on stimulation of the secretory areas of the cortex, is always thin, and generally presents all characteristic properties of the saliva obtained from the irritation of the chorda tympani. 8. Division of the latter is followed by a complete inhibition of the secretion on the corresponding side; while division of the sympathetic nerve does not manifest any influence on the secretion.

On Secondary Lesions of the Tonsils and Lingual Follicles in Pulmonary Tuberculosis.—In the Polish weekly *Gazeta Lekarska*, No. 15, 1889, p. 308, Dr. Zdzislaw Dmochowski, of Warsaw, publishes an able paper on the subject, based on his researches in Professor W. L. Brodowski's laboratory. In all, fifteen fatal cases were examined. They referred to patients of from eighteen to fifty-six, suffering from late phthisis; in five of them well-developed laryngeal tuberculosis and multiple (though small-sized) ulcers of the pharynx were simultaneously present; while in one there was found a tubercular ulcer in the nasal cavity, accompanied by fairly numerous tubercles. In every one of the fifteen patients more or less intense tuberculous lesions of the tonsils were discovered; while in ten the follicular glands at the base of the tongue were also affected in the same way. The principal results arrived at by Dr. Dmochowski may be given briefly as follows:

1. Secondary tubercular lesions of the tonsils represent an exceedingly (*nieslychany*) frequent, if not constant, occurrence in patients suffering from pulmonary phthisis. [The statement is fully in accord with that by Dr. Fritz Strassmann, of Professor Cohnheim's laboratory, who has found tonsillary tuberculosis in thirteen out of twenty-one fatal cases of pulmonary phthisis examined—*vide* Virchow's *Archiv*, 1884, vol. 96, p. 319. Meanwhile, about twenty years ago, Professor R. Virchow was teaching (*Geschwülste*, vol. ii., p. 674) that the lesions in question were extremely rare.]

2. Similar morbid changes in the lymphatic glands at the root of the tongue occur almost as commonly.

3. All facts seem to point out that both the tonsils and lingual follicles are infected from the oral cavity. Indeed, the lesions are met with only in cases of primary tuberculosis of the respiratory tracts. They

are absent when the primary affection is localised in other organs or regions (for instance, in the genital system).

4. The tubercle bacilli, when penetrating from the oral cavity into the crypts of the tonsils, and into the hollows of the lingual follicles, give rise to morbid changes, which at first remain superficial, but subsequently involve ever deeper structures. The initial alterations arise in the epithelial lining, and then in the subepithelial tissue. Soon after the penetration of the microbes into the epithelial cells, the latter become opaque, cease to take in dyes, detach themselves from the neighbourhood, etc. ; in short, the invasion of the bacilli seems to cause something like a complete necrosis of the epithelial elements concerned. The subepithelial layer undergoes inflammatory changes. Later on, the morbid process spreads to the lymphatic sinuses or spaces, and then into the follicles themselves, the changes consisting in an enormous infiltration of tissues with Koch's rods, inflammatory lesions, and the development of typical tubercles. Finally, the latter also appear in the connective tissue between the follicles, along the lymphatic vessels connecting the tonsil with the nearest cervical lymphatic glands (situated close to the large blood-vessels of the neck).

5. Both in the tonsils and lingual follicles tubercular inflammation may lead to ulceration. In the tonsils, however, the ulcers never appear on the free surface of the structure, but are always found in the crypts. But in the lingual follicles, the ulcers developing in their hollow may easily reach the surface to spread over on a more or less extensive area of the adjacent mucous membrane of the tongue.

5. In the tonsils, caseous disintegration of tubercles may occasionally (though rather rarely) lead to the formation of largish cavities (caverns).

7. When examined by the naked eye during the patient's life, tubercular tonsils do not present any special or characteristic alterations, and that even when deep-seated lesions are very intense. In the latter case, the glands may be slightly enlarged (as in cases of a well-developed faucial catarrh), and, on pressure, yield some turbid mucus or serum. Sometimes they are soft and succulent ; sometimes, on the contrary, shrunken, hard, and dry.

8. The striking tendency to the formation of intracryptous ulcers may be, probably, explained by the supposition that deeper layers of the glands furnish some more favourable life-conditions for the tubercle microbe than the external mucous lining.

On the Gastric Juice during Sleep and Wake.—In the *Vratch*, 1889, Nos. 5, 6, 7, and 8, pp. 129 and 164, Drs. S. L. Rappoport and N. S. Jdan-Püshkin, of St. Petersburg, publish each a series of independent experimental researches, which have been carried out in Professor V. A. Manasseïn's clinic, with the object to determine the effects of sleep and waking state on the secretion and properties of the gastric juice in healthy persons. By the way, the authors received each a gold medal for their work from the Conference (Senate) of the St. Petersburg Military Medical Academy. Dr. Rappoport made, in all, seventy-two experiments on fourteen men, of which thirty-six referred to such persons who were waking during day and sleeping during night ; while the other thirty-six observations concerned such subjects who were waking both during the day and night-time. The gastric juice was obtained after the usual method employed in Professor Manasseïn's clinic—that is, by means of a soft gum gastric sound, connected with a receptacle and an aspirating apparatus. The main conclusions drawn by the author from his investigations my be given thus : 1. Under the influence of sleep, the proportion of free hydrochloric acid in the gastric juice, as a rule, decreases to a considerable extent. 2. The acidity of the juice is also diminished very markedly. [In waking state, it oscillated between 0·34 per cent. and 0·07, being in the average 0·21 per cent. Meanwhile, during sleep, it varied between 0·19 and 0·0, the average figure being equal only to 0·08. In other words, the acidity diminished full sixty-two per cent.] 3. The amount of the juice (secreted under the influence of a stimulating agent, such as the internal administration of hard-boiled egg's albumen) decreases. [In the average, it falls from thirty-two cubic centimetres, as obtained during day, down to thirty-two during sleep.] 4. The digestive power of the juice becomes much weaker. [Given a certain quantity of egg's white, a day juice digests, on the average, eighty per cent. of the substance ; while the juice secreted during sleep can digest not more than twenty-nine per cent., that is, the digestive power decreases 63·75 per cent.] 5. The proportion of pepsine and Hammarsten's rennet ferment seems to remain unaffected by sleep. 6. Hence, the said diminution in the digestive power is dependent upon a decrease in the proportion of free hydrochloric acid. 7. As to the time of the appearance of various products of the gastric digestion, it seems to remain unaffected by sleep.

Dr. Jdan-Püshkin's experiments were conducted after the same methods as Dr. Rappoport's. In all, sixty-four observations on fourteen healthy men, aged from eighteen to twenty-four, were made. The results may be summed up as follows: 1. Night sleep manifests a depressing influence on the secretion of the gastric juice, since (*a*) the acidity of the juice decreases (being equal, on an average, to 0·256 per cent. in waking hours, and only to 0·069 during sleep) ; (*b*) the acid reaction (that is, the proportion of free acid) is diminished [The reaction was present in all waking persons, but proved to be absent in twenty-six, and diminished in its intensity in the other three sleepers] ; (*c*) the digestive power of the juice weakens, the failure being dependent upon a considerable decrease in the proportion of free hydrochloric acid, as well as upon a slight diminution in the secretion of pepsine ; (*d*) the proportion of peptones sinks. 2. As to waking during night, it almost does not affect either the secretion of the juice, or its properties. [Therefore, the authors' researches fully confirm the statements published in the *Vratch*, No. 47, 1887, p. 925, by Dr. P. V. Burjinsky, who having carried out ten experiments on six healthy medical male students in Professor Manasseïn's clinic, came to the following conclusions : 1. During night sleep, the acidity of the gastric juice very markedly lessens comparatively with that in waking hours (the average day acidity was 0·16 per cent., the night one, 0·06 ; the decrease amounted, therefore, to 62·5 per cent.) 2. The diminution of the acidity advances parallelly with that in the proportion of free hydrochloric acid. The latter was determined by means of phloroglucin-vanillin, proposed first by Dr. A. Guenzburg, and subsequently recommended by Dr. Burjinsky, Professor Ewald, and many other authors, as the best test for the acid.]

Creolin in Surgical Practice.—In the *Revue Médicale de la Suisse Romande*, June, 1889, p. 361, Dr. Roux, House Surgeon to L'Hôpital Cantonal de Lausanne, details his extensive experience in regard to creolin as a surgical antiseptic and deodorising agent. The following points of practical interest, emphasised by the distinguished surgeon, deserve to be placed before our readers : 1. In cases of recent wounds (sutured or otherwise), he applies successfully gauze soaked in a two per cent. creolin emulsion. He resorts to the dressing, however, only in such patients "in whom neither phenol nor corrosive sublimate can be used, while an antiseptic more reliable than iodoform is required." 2. Creolin possesses a powerful deodorising property, and, hence, may be employed with best results in cases of offensive ulcers or decomposing tumours. 3. In cases of catarrh of the bladder, intra-vesical injections of from a half to one per cent. emulsion of creolin give by far more satisfactory results than those of boracic acid solutions. [An antiseptic action of which Dr. Roux regards as "*plutôt morale que prouvée.*" Professor Nikolai F. Miller, of Moscow, thinks otherwise, and even recommend boracic acid as the best possible antiseptic means in the new-born and infants, which, while being quite innocuous, is fully effective, and hence deserves to be introduced into an universal use. Vide the *Sei-I-Kwai Medical Journal*, February, 1889, p. 35.—*Reporter.*] 4. A two per cent. creolin emulsion is very serviceable for repeated intra-uterine and vaginal irrigations—at least, "in such cases where corrosive sublimate may be deemed dangerous and weak carbolic solutions insufficient." 5. The same solution proves to be useful for irrigating the nasal, oral and pleural cavity, the aural region, etc. 6. Creolin plugs rapidly remove offensive smell in ozæna. 7. On the whole, in hospital practice, creolin may be resorted to as a satisfactory substitute for phenol, corrosive sublimate, and iodoform "in all cases where a powerful deodorisant, or a less dangerous and yet reliable antiseptic is required." With regard to private or rural practice, creolin alone may be used in all cases of minor or rare (*rares*) operations. 8. Creolin, however, cannot be employed for disinfecting instruments, and that partly because of its lack of transparency ("*la recherche des instruments y est une vraie pêche au petit bonheur*"), partly on account of its giving a "soapy touch" to nickel, ligatures, etc. 9. In regard to a stimulating action on granulations, creolin is by far inferior to iodoform. 10. Its main advantages consist (*a*) in its being by far less irritant than carbolic acid ; and (*b*) in its being out of any comparison less toxic than corrosive sublimate. 11. Still, its use requires certain caution, since Dr. Roux happened to observe several times diarrhœa and a rather striking loss of flesh following after a several days' use of creolin in the shape of irrigations or compresses.

Sulphonal as a Hypnotic in Insanity.—Dr. Alexandr J. Malshin, House Physician to the Prëobrajensky Asylum, Moscow, says (*Novosti Terapïi*, No. 22 and 23, 1889, p. 389), that having tried sulphonal in a number of cases of various mental affections, he has arrived at the following conclusions : 1. When given in two-gramme doses at bed-time, the drug, as a rule (but by no means always), brings about sleep which comes in from one to three hours, to last from two to twelve. 2. In organic cerebral disease, sulphonal remains "almost inert." 3. On awakening, the patient always feels depressed and drowsy; while some, in addition, complain of headache and "sensation of being intoxicated" (as if from alcohol). 4. The drug invariably gives rise to general prostration, and inorganic brain disease, to weakening of the pulse. 5. Apparently, it does not produce any impression on the patient's mental condition.

Milk as a "Cure" for Bee-Stings.—According to the *Novosti Terapii*, Nos. 22 and 23, 1889, p. 342, the *Kamminer Kreis-Zeitung* records an instructive case demonstrating a striking remedial value of cow's milk in cases of stinging by bees. An infant, a twelvemonth of age, managed to get near to a bee-hive, and in a minute received as many as thirty-five severe bites about the head, face, and hand. The patient's parents, almost mad from despair, at once began to extract the insects' stings from the greatly swollen and inflamed parts, and to freely apply to the latter fresh milk. In a couple of hours the swellings had all disappeared, and by the night-fall the infant returned to its former best possible state.

V.—OBSTETRICS AND DISEASES OF WOMEN.[1]

The Medals of Benjamin Rush, Obstetrician.—Dr. Horatio R. Storer called forcible attention to the fact that to Dr. Rush was due the first suggestion, or rather prophecy, of obstetrical anæsthesia. He quoted various passages from Rush's works which demonstrated that he was a skilful obstetrician. In the title of one of his papers he closely associates the pains of labour with its dangers, announces that they can both be lessened, recognizes that they are the potent cause of subsequent disease, and teaches their prevention. Particular attention was called to the following statement of Rush: "I have expressed a hope in another place that a medicine would be discovered that should suspend sensibility altogether, and leave irritability or the power of motion unimpaired, and thereby destroy labour pains altogether." The importance of this extraordinarily-interesting passage seems to have been recognised only by Channing, Gaillard Thomas, and Faget of New Orleans. It was lost sight of entirely during the ether-chloroform controversy. Exhaustive research has been made by the author, aided by Dr. Toner, of Washington, which has resulted in failure to find any other reference to it; and similar want of success has followed the studies of Drs. Chadwick, Gaillard Thomas, and Mundé, to whom the author appealed as those who were most familiar with modern obstetric literature.

Dr. Storer exhibited enlarged photographs of the two extremely rare medals of Rush which are in his collection, and expressed the hope that they would be of use in giving the correct features of the "American Sydenham" when his monument, undertaken by the Association, shall be raised, and that the paper itself might tend toward a better appreciation of the true merits of the man himself.

Note on the Use of Boracic Acid in Gynecic Practice.—Dr. W. W. Potter, of Buffalo, first used boracic acid as a substitute for iodoform on account of the bad effect of the latter upon the hands. He found that boracic acid delayed decomposition of uterine and ovarian discharges, and that a tampon could be retained for a week without discomfort or annoyance when this antiseptic was used. In his experience it had also been of service in cases in which sterility existed, and he believed it exerted such chemical action upon the uterine secretions that fecundation became possible. He had also found it one of the best dressings for operative wounds of the female genitals.

Inversion of the Uterus; Reduction by a New Method; Exhibition of the Instrument.—Dr. H. O. Marcy, of Boston, said that inversion may be partial or entire, and is probably more frequent than is usually supposed, especially in the practice of midwives. The shock and hæmorrhage attending the accident are usually severe, and it is not unusual for the patient to succumb within a very short time after the accident has occurred. Hence the principle that reduction should be accomplished as soon as possible, the patient being then kept upon her back, with the vagina tamponned for a sufficient period. The methods of reduction of Emmet, Noeggarath, and Thomas were described and commented upon. Spontaneous reduction could occur, but it was thought that it rarely did. The first systematic attempts at reduction were reported by Prof. J. T. White, of Buffalo, in 1858, Tyler Smith reporting his method in the same year. The method of Winey, of Boston, was thought to be sound in principle, and it had been successful in practice. Barnes' suggestion, that lateral incisions should be made in the cervix before attempts were made at reduction, was also a good one, and had been followed by good results. Thomas's method was once considered bold, though ingenious; but now that laparotomy is so frequently performed it would be adopted with hesitancy. It has been demonstrated, however, that it may be unsuccessful. The author's method was then described, the principle being that traction was applied to the cervix while an equal amount of pressure was applied to the fundus, the opposing forces harmonizing and quickly effecting reduction. The present perfected instrument was reached after a long series of experiments, and has been tried in one case, in which complete reduction was effected in twenty-six minutes. The method consists in passing four stout ligatures through the cervical tissue at equal distances from each other, and these are attached to two parallel rings or hooks upon the side of a long shaft, the hooks working in slots. At the end of the shaft is a hard-rubber cup which receives the fundus. The shaft contains a screw, which is worked by a nut at its lower extremity, the shaft being graded in pounds up to fifteen, according to the number of turns of the screw. As the screw is turned the cervix is dragged down, and at the same time the fundus is pushed upward and through it.

A Series of 500 Cases of Confinement in a Maternity.—Dr. Joseph Price said there had been no deaths and no septicæmia in this series, the institution in question being the Preston Retreat, in Philadelphia. Absolute cleanliness of person and surroundings, abundance of water, soap, and pure air were the means which had yielded such gratifying results. Of these cases fifty-two had been cases of instrumental delivery, many of the mothers having contracted pelves. There was one case of placenta prævia, three of twins, also several face and breech presentations.

Application of Forceps in Transverse and Oblique Positions of the Head, with a Description of a New Forceps.—Dr. Fry, of Washington, said he had sought to obtain the views of many practitioners as to their method of using forceps, and had addressed them in a circular letter. This brought eighty-two responses, of which forty-two stated that the custom was to apply the instrument to the sides of the head; thirty-one others applied to the sides of the pelvis, and in the others the method was indifferent. The author's instrument was curved on the flat, and could be applied in either transverse or oblique positions to the bi-parietal diameter of the fœtal head. Many cases in which there was death or paralysis of the fœtus, were those in which the blades of the ordinary instrument were not at the sides of the pelvis, its pelvic curve being a source of injury when applied in the conjugate diameter. The posterior blade of the author's instrument has both a cephalic and a pelvic cure, the anterior has only the cephalic curve. The instrument has also a screw for the regulation of the compression and a traction rod which is attached to the anterior blade and aids in bringing the head down to the brim of the pelvis.

When should the Obstetrical Forceps be used, and what form of Instrument is required?—Dr. William S. Stewart, of Philadelphia, said that such conditions as eclampsia, exhaustion, uterine inertia, large or impacted fœtal head, called for the use of obstetrical forceps. The membranes must also be ruptured, the os dilated and its lips retracted; there must be a knowledge of the position of the child, the bladder and bowels must be empty. It would seem to be self-evident that one should use the instrument with which he was most effective. An Objection to the ordinary forceps with crossed handles was that, while it was easy of application for the first position, it was difficult or dangerous for the second. Hence the author's instrument, in which the handles are parallel and do not cross. It has also a second joint to the handles and hand-piece, the traction being entirely accomplished with the latter. The blades may be those of the Simpson, or Hodge, or Wallace forceps. The traction and compression with the author's instrument are regulated by the resistance offered; also the principal joint in the handles is not fixed, so that there may be very complete adaption of the head to the pelvis. Either blade can be applied first, and, in the author's opinion, the instrument insures greater safety to the mother and child than by customary means, and greater ease to the accoucheur.

Pathology of Ectopic Pregnancy and Pelvic Hæmatocele.—Dr. W. H. Wathen, of Louisville, based his argument upon the following premises—viz.,

1. The ovum is never impregnated in the uterine cavity, and the conjugation of the male and female elements must take place before or just after the ovum enters the tube.

2. Ectopic pregnancy is always primarily tubal, with the possible exception of ovarian pregnancy; the tube usually ruptures before the fourteenth week into the folds of the broad ligament or into the peritoneal cavity.

3. Abdominal pregnancy cannot occur except as a result of primary or secondary rupture; and if the villous or placental attachments are destroyed, the ovum immediately dies, because it cannot form secondary attachments to other structures.

4. If, in rupture into the peritoneal cavity, the ovum retains villous or placental attachments, it may be possible, under certain conditions, for the pregnancy to continue, though this is not probable. If the amnion is ruptured in the early months, the embryo or fœtus will die.

5. So-called interstitial pregnancy does not always rupture into the peritoneal cavity, though it usually does.

[1] American Medical Association, Newport Meeting, June 25th, 1889.

6. If we define pelvic hæmatocele as an encysted or confined tumour formed of blood, then intra-peritoneal hæmatocele is not possible.

Tait is almost alone in his belief that in normal pregnancy the conjugation of the two elements takes place in the uterus, and the author does not think his premises upon this subject are correct, nor his conclusions logical. His assertion that the spermatozoids cannot pass out through the Fallopian tubes unless disease has destroyed the ciliated epithelium, is based upon no positive evidence, and is contrary to what has been proven in observations upon the lower animals. The ciliated epithelium has no effect upon the movements of the spermatozoids, and their inherent power of movement is proven in those cases in which women have become pregnant with a nearly imperforate hymen, and with atresia vaginæ with only a small fistulous and diseased canal leading to the uterus. If the ovum is not impregnated before, or just after, it enters the tube, degenerative changes will destroy its vitality before it reaches the uterus. If, after impregnation has occurred, the surfaces of the endometrium were not in immediate contact, the ovum would gravitate to the lower segment of the uterus, causing placenta prævia, or else it would pass out into the vagina. The ovum cannot form villous attachments until it is held immovably in the maternal structures, and this is not possible, except in the tube or in the uterine cavity. The reports of ovarian pregnancy are numerous, but they seem to be based upon insufficient evidence. In none of them has ovarian stroma been found unless confined to one side of the sac, and this may easily be due to tubal pregnancy in which rupture has occurred into the folds of the broad ligament.

Parry's statistics of ovarian or abdominal pregnancy were all collected from imperfect or mutilated records made by men of no experience in microscopical and pathological research, and they are practically of no value as proof that pregnancy may primarily occur outside the tube. Ectopic pregnancy may occur at any point in the tube, from a short distance within the fimbriated extremity to the uterine cavity, and is caused by partial or complete closure of any part of the tube, which is usually the result of desquamative salpingitis. It is improbable that tubal pregnancy continues in any case until term, rupture usually occurring prior to the fourteenth week either into the folds of the broad ligament or into the peritoneal cavity. Primary intra-peritoneal pregnancy is impossible, because the ovum cannot be held securely in any one place and form the necessary attachments. The ovum precipitated into the peritoneal cavity dies, therefore, for want of nutrition.

The placenta in extra-peritoneal pregnancy may attach itself to the uterus, omentum, intestines, pelvic and abdominal wall, etc., by stripping off and carrying before it a layer of peritoneum, and many such cases have been reported as abdominal pregnancies. In the latter months of pregnancy the ovum may possibly continue to develop in the abdomen after rupture of the amnion. In intestinal pregnancy there is *usually* rupture into the peritoneal cavity, but *not always* as Tait asserts.

Pelvic hæmatocele sustains such intimate relations to ectopic pregnancy that it is not easy to describe the pathology of the one without referring to the other. Pelvic hæmatocele is usually considered an encysted, intra- or extra-peritoneal blood tumour in the pelvis, which may extend into the abdominal region. The author does not believe it possible for an accumulation of blood in the peritoneal cavity to become encapsulated, so as to form a well-defined tumour in the pelvic or abdominal cavity. If it were possible to have encysted intra-peritoneal hæmatocele, why does it never occur after abdominal sections for the removal of a diseased tube, ovary, or uterus? Encysted hæmatocele may result from a sudden cessation of a pseudo-menstruation that sometimes follows laparotomy, but in such cases the blood is effused into the areolar tissue under the peritoneum, and not into the abdominal cavity. A blood tumour may extend above the pelvis, and even to the umbilicus, but this does not indicate that the hæmorrhage has been into the peritoneal cavity. In intra-peritoneal hæmorrhage no well-defined tumour can be felt *per vaginam* or by abdominal palpation, while in extra-peritoneal hæmorrhage an error in diagnosis is hardly possible. Intra-peritoneal hæmorrhage is almost always caused by primary or secondary rupture of a tubal pregnancy, and the shock and other evidences of internal hæmorrhage will usually point to the cause.

The treatment indicated in abdominal section and ligation of the bleeding vessels. Encysted hæmatocele may be caused by sudden metrostaxis of normal menstruation, or pseudo-menstruation following abdominal or pelvic operations, or by rupture of a tubal pregnancy into the folds of the broad ligament. The symptoms are sudden access of pain, faintness, accelerated pulse, and, possibly, elevation of temperature. The tumour may not be felt above the pelvis, or there may be a well-defined, fluctuating tumour extending as high as the umbilicus. The diagnosis is less readily made if the case is not seen until some days after the hæmorrhage has occurred. Extra-peritoneal hæmatocele usually results in speedy recovery, with suitable care and precautions, the blood being absorbed. Suppuration or rupture into the peritoneal cavity rarely occurs. Should there be symptoms indicating that either of these conditions has occurred, the abdomen should be opened, the cavity thoroughly cleansed, and a drainage tube introduced. If fluctuation is felt *per vaginam* the tumour should be entered through the vaginal vault, otherwise laparotomy should be performed.

Casuistry in Obstetrics.—Dr. T. Parvin, of Philadelphia, said that questions of conscience must always be recurring in the course of the practice of obstetrics. It might be said that all law in all civilised lands is only casuistry. Among the questions of consequence which are proposed to the obstetrician for answer is that of Comte: "If the object of pregnancy is the perpetuation of species, and cohabitation during pregnancy is a source of danger to the fœtus, should cohabitation be allowed?" The author would answer this question decidedly in the negative, considering that it is improper, immoral, unjust, and injurious to both mother and fœtus. Another pertinent question was:

"Should a doctor inform his patients as to the means of preventing pregnancy, admitting that he had the knowlege?" The reply was, that such information would usually be unwise, for though there might be excuse for such information on the score of serious disease in the parents, or inability to protect and support children should they be born, such information was usually extensively disseminated, and its influence would be pernicious. The question as to the propriety of artificial miscarriage is also an important one, and the justifiability of the operation was recognised in such cases as those in which blindness would result from the continuation of the pregnancy.

Such operations as amputations of the pregnant uterus were considered justifiable in certain cases of great pelvic deformity, and the testimony of Tait in this matter gives weight to such an opinion. It must also be admitted that there are also cases in which embryotomy or craniotomy, or some other destructive operation, is not only justifiable, but imperative in the interests of a parturient woman. This statement did not at all conflict with that which had reference to the usefulness of the Cæsarean section. The latter operation should be preferred to craniotomy in those cases in which the conjugate measured two inches or less.

Pelvic Abscess in the Female.—Dr. William H. Parish, of Philadelphia, believed that the existence of pus in the areolar tissue was rare compared with its existence in the pelvic cavity or the organs of the pelvis. He would divide pelvic abscess into three varieties: 1, areolar abscess; 2, intra-tubal and ovarian abscess; 3, intra-peritoneal abscess. The first form is usually a sequel of labour, the latter having been severe and accompanied with more or less injury to the uterus, the cervix, the vagina, etc. Secondary areolar abscess may occur, however, from gonorrhœa, from hæmatoma, etc. He believed that so-called chronic cellulitis, without precedent inflammatory disease of the pelvic organs of some kind, did not exist. The second form usually involved both the tubes and the ovaries, and was more frequently seen than the first. Associated with this there might be a plastic inflammatory condition of the pelvic peritoneum. The term pyosalpinx gave little idea of the extent of this form of pelvic abscess which was possible. Intra-tubal abscess was very frequently due to gonorrhœa, which frequently occurred in young married women, though it might not appear for some months after marriage. It might also come from various forms of traumatism, from septic infection other than gonorrhœa communicated from the uterus.

Septic salpingitis and ovaritis frequently occurred after abortion, in fact rather more frequently than areolar abscess. The careless use of uterine sounds and tents was also responsible for many cases of this condition. In treating either of these two forms of abscess a high degree of operative skill is requisite. Another requisite, in order to a successful issue, is perfect drainage. Aspiration of such cases is usually not advisable, and is fraught with danger. If there is bulging and fluctuation in the vagina, an incision through its wall is indicated. If by such incision an intra-tubal abscess is opened, it may be recognised by the fact that the walls of the abscess sac are smooth to the feel, and also do not collapse. In most cases it is quite inadvisable to operate through the rectum. In any case in which an incision is made, care should be taken to avoid pulsating vessels. Likewise, in placing a drainage-tube it must be provided that it does not come in contact with the wall of a large-sized bloodvessel. If the abscess involves the tube, the necessary treatment is laparotomy with removal of the diseased structures, and the insertion of a drainage-tube. Cases have been reported in which intra-tubal abscess has been cured by drainage through the uterus, but such cases are believed to be of very rare occurrence. The method of stretching the edges of the abscess-sac into the abdominal wall, as advocated by Tait, is not considered desirable for most cases.

The intra-peritoneal variety of pelvic abscess is that in which the pus is in the pelvic cavity. It is not so frequent as that which proceeds from diseased tubes. It may occur from the leakage of pus, from a pyosalpinx into the peritoneal cavity, from a peritonitis, from lymphatic

inflammatory conditions, from initiating ligatures after abdominal section, etc. The quantity of pus in the abscess may be small or it may be very large. In one of the author's cases the quantity was two gallons. In all cases of this variety there should be early operation. Should a fistulous tract result it not infrequently indicates want of skill on the part of the operator.

Tetanus following Ovariotomy.—Dr. Joseph Taber Johnson, of Washington, said it was primarily the report of a very rare case. The patient was sixty years of age, and an abdominal section was believed to be indicated. A small ovarian cyst was removed, a drainage-tube being introduced, and all progressed favourably until the twelfth day. At that time symptoms of tetanus appeared, which increased in intensity until the fifteenth day, when the patient died, with evidences of heart failure. Careful investigation was made, but it was believed that the author's hospital, in which the operation was performed, was in a perfectly sanitary condition. The author's horses were also without disease, and the author's hands were free from injury; the horses had not been driven by him for some days. This complication has reported only a few times, and has usually occurred within a few days after the operation. Bernouil recently announced his belief that it was communicated to human beings by horses, the medium being a bacillus. This should teach all who do abdominal sections to avoid the possibility of infection from horses.

The Injuries of the Bladder during Laparotomy, including a Report of Sixty-seven Cases.—Dr. A. Reeves Jackson, of Chicago, collected his data from various sources. Some of the cases had been already published, but the greater number had been obtained through personal correspondence with the operators in whose practice the accidents had happened, and were now made known for the first time. Of course, it was admitted that the list was incomplete. Some surgeons manifest a reluctance to make known the various mishaps which occur in their operative experience, perhaps with the belief that a knowledge of them might injuriously effect their reputation among their colleagues. The author considered this an error of judgment. Surgeons should be honest as well as skilful, for their integrity would be quite as likely to receive recognition as their dexterity, and was certainly of greater value.

Considering the conditions under which bladder injuries may occur during laparotomy, it was not necessarily discreditable to any surgeon to meet with them, for they might not be due to any carelessness or lack of skill on his part. In many of the cases cited no possible degree of diligence could have averted the accident. Adhesions of the peritoneal surface of the elongated bladder to the anterior abdominal wall, frequently could not be known in advance, and their existence was only demonstrated after the viscus had been opened. The use of the catheter as a means of diagnosis was not always available, because the compression of the bladder against the pubes might prevent the introduction of the instrument beyond that point. Certainly, this attempt should always be made in any case of suspected difficulty, and would seem to be even a proper and unobjectionable routine method.

Another useful precaution was to avoid prolonging the abdominal incision toward the pubic bone until the opening into the peritoneum had permitted the relations of the bladder to be ascertained. The mortality of the cases in which the bladder had been opened was large, being about thirty per cent., but this was due to the complicated and serious character of the cases in which the accidents had occurred, the consequently increased length of the operation, and the greater danger from shock, rather than to the mere vesical injury.

The latter did not seem, in itself, to be very important as influencing the recovery of the patient, but should a fistula occur it would signify great discomfort, and also chagrin and annoyance to the surgeon. Inasmuch as the bladder was recognisable with more difficulty when empty than when full, it would be better in cases which presented doubtful features to commence the operation with the viscus more or less distended. When its position had become known, it might be emptied by an assistant.

As to the treatment, if an opening should be made it should be closed at once with a continuous suture of catgut or fine silk, the serous surfaces of the wound being inverted, and a permanent catheter being used for two days. At the end of that time it may usually be dispensed with. If the wound exceeds two or three inches in length, the catheter should be retained three or four days longer; and in all cases the catheter should be retained as the urine contains blood. Should urine appear at the abdominal wound subsequent to the operation under conditions which would make it dangerous or inexpedient to reach the seat of the vesical injury, the catheter should be used continuously or at short intervals to lessen the quantity of urine which escapes through the fistula and thus aid in its closure. If the fistulous opening shows no disposition to close after two or three months, the edges should be freshened to the depth of half an inch or more, and stitched together.

In exceptional cases it may be expedient to affix the wounded edges of the bladder with those of the abdominal incision, in the manner detailed by Thomas and others, but as this plan must interfere with the subsequent contractility of the bladder, it is not to be commended as a customary practice. The suturing and dropping of the bladder is the better method.

Pelvic Cellulitis. By A. C. J. Skene (*Analetic*, June, 1889).—By this term is to be understood inflammation of the pelvic cellular tissue in the suppurative stage. The author's experience comprises some complications of this condition which are unique so far as his knowledge extends, as he has failed to find any records of similar cases. The cases of extension of inflammation, from the broad ligament to the sheath of the psoas muscle, and burrowing of pus outward and upward, are cited, in one of which the diaphragm was perforated and the pus discharged into the bronchi. In two false anchylosis of the hip and knee joints were present. The following summary of his views is given by the author:—

1. That pelvic cellulitis, uncomplicated, occurs frequently.
2. That sub-peritoneal pelvic hæmatocele should be recognised as one of the causes.
3. That aspirating may be employed before and after suppuration, with advantage in suitable cases.
4. That abscess in the cellular tissue of the pelvis should be opened from the vagina when the conditions are favourable.
5. That laparotomy is advisable when the vaginal wall is not closely adherent to the abscess sac.
6. That laparotomy should be made when a pelvic abscess opens into the bladder and suppuration continues.
7. That cellulitis may extend to the psoas muscle, and give rise to psoas abscess.

On Induction of Labour in Kidney Disorders during Pregnancy. By E. L. Partridge (*Analectic*, June, 1889).—The author is sceptical as to the occurrence of true convulsions in connection with parturiency without an accompanying disturbance of the renal function. The cases which seem to unsettle such a belief may be only apparent exceptions to the rule, as often the urinary signs and uræmic symptoms are of the slightest and most erratic character, and often the albuminuria may be absent on the day on which the urine is examined. As to interference with gestation in cases presenting signs of renal disturbance, no general rule can be formulated. The history of previous uræmic attacks during former pregnancies should always make the question of arresting gestation a prominent element in the problem of treatment to be solved, and this should be answered in the affirmative in case any evidence of the same complication should be observed in the case under consideration. The author holds that the danger of a chronic nephritis, induced by the repeated attacks of the functional renal disturbance, is too great to be overbalanced by the desire to save the child, or by its rights, as there is every reason to believe that spontaneous abortion and eclampsia will follow, if an expectant plan of treatment be adopted in such a case, and that both mother and child will be lost, by temporizing, after symptoms of uræmia have developed, in the larger number of cases. The histories of three cases are reported, all bearing on this point of organic renal disease resulting from successive attacks of puerperal uræmia, but only presenting symptoms during the existence of the pregnant state, two of which were fatal after premature labour had been induced, and the other one of recovery after spontaneous abortion at the beginning of the third month, although grave symptoms of uræmia, not preceded by any urinary signs developed immediately after the miscarriage, but gradually subsided. The symptoms of uræmia developed in all immediately after delivery, and the amount of albumen found in the urine before labour was insignificant or a mere trace. His own conviction is that in every case in which chronic nephritis exists, the immediate interruption of the pregnancy is strongly indicated. In "puerperal albuminuria," the purely functional disease, action in arresting gestation should depend on the amount of albumen excreted; its tendency to increase or diminish; the presence or absence of symptoms and the general condition of the patient. In forty per cent. of his cases of this condition he had induced labour. Vomiting, visceral, disturbances, and marked decrease in the amount of urine excreted are to be regarded as grave symptoms, and demand an exercise of great vigilance and readiness for action on the part of the physician. In the discussion, following the reading of the paper, the author expressed the opinion that in the treatment of eclampsia venesection was preferable to the use of the veratrum viride in the majority of cases.

The Spirit of the Societies.

British Gynæcological Society (Fancourt Barnes, M.D., vice-president, in the chair). **Twisted Pedicle.**—Dr. Edis exibited an ovarian cyst where the pedicle had become twisted and the cyst strangulated. F. W——, æt. thirty, was delivered of a fine child, after a good labour, on March 18th, 1889. The abdomen remained swollen, so that it was thought there was another child. On the evening of May 11th she was seized with violent pain, shooting from the left side to the back. This subsided in a little time, but came again with renewed violence the following evening. She suffered intense pain in the left lumbar region, spreading from thence towards the middle line of the body, and backwards to the spinal column. She also suffered from severe vomiting. On the 17th she was removed to the Chelsea Hospital for Women, where ovariotomy was at once performed. The cyst, as large as the pregnant uterus at the eighth month, was full of a dark greenish coloured fluid, evidently from hæmorrhage having occurred into the cyst. There was also effusion of blood between the walls of the cyst on one side, where it was of the consistence of the spleen. The pedicle, which was formed by the broad ligament, was twisted about one and a half turns from left to right. The right ovary being enlarged and cystic, was also removed. Sickness was troublesome for the first few days after operation, but the patient made a perfect recovery. Remarks were made by Mr. Lawson Tait, Dr. Barnes, Dr. R. T. Smith, and Dr. Purcell, to which Dr. Edis replied.

Cyst of Broad Ligament.—Dr. R. T. Smith showed some silk ligatures which had come away from a patient, æt. seventy-three, from whom he had removed an ovarian tumour five months previously. A cystic swelling, reaching to the umbilicus, had recently developed, and at the operation it was found to spring from the broad ligament. The internal lining was easily enucleated with a few touches of the cautery applied in its deepest portion, where the adhesion was most intimate. The sac was then closed with ligature as low as possible, and left as an ordinary pedicle; it was tied with three loops with stout silk. A drainage tube was left in the abdominal cavity, but was removed the next day as there was no hœmorrhage. For seven days the progress of the wound was uninterrupted, and the wound healed. On the eighth day the dressings were found saturated with a brownish colored sour swelling fluid, and the discharge continued for three months. The patient was sent to the sea-side, having a small india-rubber drainage tube in the wound. On her return the sinus was found to be six inches deep. A fortnight later the thin looped ligature came away, and the wound was healed ten days after, and the patient quite well. Dr. Smith said that the cure might have been quicker if the sac had been drained from the first.—Dr. Bantock said it was his practice to shell out the cyst from the wall proper, and if the base was so large as to make ligature unsafe, he stitched the cyst to the parietes.—Mr. Lawson Tait said since Dr. Myer's paper he had enucleated all cysts of the broad ligament. Once the cyst-proper was out, drainage was a matter of the greatest ease, the tube being passed into the pocket of the cellular tissue. Hæmorrhage was not to be feared, and it was a matter of indifference whether they stitched the cyst to the abdominal walls or not.—Dr. Edis said they learnt from that case that silk ligatures were not absorbed so easily as they might imagine. The one shown was scarcely altered at all.

Edinburgh Medical Society (John Smith, M.D., president). **Intestinal Obstruction.**—A discussion on the above subject was opened by Dr. G. Miller, who, for practical purposes, made a triple subdivision: (*a*) acute obstruction, (*b*) subacute, (*c*) chronic. Exact diagnosis was always difficult, but especially so in cases belonging to the second group. Five cases were described, all of which proved fatal. This result was doubtless due in part to the delay preceding the operation. When operation should take place would always prove a difficulty.—Mr. Duncan inclined to divide the cases into acute and chronic. The point the most difficult was the diagnosis, as other conditions might be confounded with obstruction. There were various conditions of the bowel wall, or external to the wall. There were also internal conditions, and there were certain reflex conditions, all of which might give rise to symptoms somewhat similar to those of true obstruction. He (Dr. Duncan) described a case which had been presented to him in which alarming symptoms marvellously like those of obstruction were found to be reflex in origin and dependent on an inflamed testicle only partially descended. In connection with obstruction due to a mass of fœces, Mr. Duncan spoke of the occasional value of the long tube, which might be passed further up into the intestine than was usually supposed. With it he had succeeded in breaking down such a mass situated high up, which had resisted other treatment and given rise to serious apprehensions.—Dr. Affleck stated that some cases of apparent obstruction were amazingly tractable. He had more than once reduced intussusception in children by means of inflation with bellows. His experience of operation was unfavourable.—Mr. Cathcart stated that he thought more might be made of the analysis of individual symptoms. Thus, in studying pain, they must observe accurately its seat, its character, whether constant or intermittent, and whether accompanied by tenderness on pressure. As a rule this latter condition would be found to be associated with peritonitis. So in respect to vomiting; it was usually supposed to be ominous when a simple belching of fluid occurred without actual retching.—Dr. William Russell spoke of the difficulties of exact diagnosis, illustrating his remarks from the records of *post-mortem* work. Drs. James Young, Kennedy, Laird, Wallace, Stiles, and Scott Lang also spoke.

The Public Health Medical Society (Sir Charles Cameron, president, in the chair).—The annual meeting of this society was held at the end of June in the Holborn Restaurant. The report of the Council was read by Dr. F. J. Allan, the secretary, and adopted by the meeting. It shows the society to be in a prosperous and working condition, and the narrative of the work of the past year shows the important duties the society performs, not only on behalf of medical men holding Public Health qualifications, but also in maintaining the standard of excellence of the examination relating to this branch of medicine.—A letter from the General Medical Council was read, in which it is stated that the Council had considered the letters sent by this society, and in consequence had laid down special resolutions respecting Diplomas in State medicine, and had requested the various medical licensing bodies to report what steps they proposed to take to bring their regulations into conformity with the Council's resolutions. The president of the Medical Council also directed the society to be informed that the registration of any new State Medicine Diplomas of the University of London is suspended until further consideration had been given to the matter.—The following gentlemen were elected officers and council of the society:—President, Sir Charles A. Cameron; Vice-presidents, Sir Joseph Fayrer, Sir John Simon, Sir Douglas Maclagan, and Dr. Alfred Carpenter; Treasurer, Dr. William Robert Smith; Council, Drs. P. Hinckes Bird, William Collingridge, John E. Cooney, W. W. Day, David F. Finlay, G. H. Fosbrooke, H. A. Fotherby, T. W. Grimshaw, Alfred Lingard, J. W. Moore, Bonner H. Mumby, A. Campbell Munro, Arthur Newsholme, J. A. Russell, E. J. Slade-King, Henry Smith, Joseph Smith, W. E. Steavenson, John F. J. Tykes, John F. W. Tatham, W. N. Thursfield, B. A. Whitelegge, E. F. Willoughby, W. C. Wise; Honorary Secretary, Dr. Francis J. Allan. The President returned thanks for the honour done him in returning him a second year to office, and desired to record the assistance he had received from the executive officers of the society. Professor W. R. Smith and Dr. F. J. Allan were elected to represent the society on the General Committee of the International Congress of Hygiene and Statistics, to be held in London in 1891.

Royal Academy of Medicine, Ireland.—D. W. J. Smyly in the chair. **Specimens.**—Dr. Baggot exhibited three specimens. The first was a myoma of the uterus which had been removed in the Rotunda Hospital by Dr. Macan by means of superficial vaginal amputation. The second an ovarian tumour, removed on May 17th; and the third a small ovarian tumour, removed on the 3rd. In the last two cases the patients had made perfect recoveries.—Dr. Horne exhibited an ovarian tumour, removed by Dr. Coppinger from a girl in the Mater Misericordiæ Hospital on the previous Saturday. The patient was a girl of seventeen or eighteen years of age. About six months ago while running she tripped over a stone trough, and fell, hitting her left side against it. On that day she did not feel much inconvenience, but on the following day she had a good deal of pain in the left lumbar region, and was obliged to go to bed, where she remained three days. She sought no medical advice at that time. At the end of two months she began to suffer from a good deal of pain immediately under the left ribs, for which she sought medical advice. The doctor who examined her found a tumour lying immediately below the spleen. But what she remarked about the tumour was that when she stood up it fell down, but when she lay down in bed at night it rose up out of the pelvis, immediately under the left ribs. She only had pain at night, which prevented her from sleeping. There was a good deal of doubt at that time as to whether it was an ovarian tumour or a displaced cystic kidney. Under the circumstances Dr. Coppinger determined to make an incision in the abdomen so as to see the tumour, which was not very much bigger than an orange. He first made an incision of about two

inches long. The tumour was then high up under the left ribs, and he (Dr. Horne) had to push it down to the wound, where it was punctured by Dr. Coppinger, and removed without difficulty. It had a very large pedicle, which had allowed it to move freely over the abdomen.

The Diagnosis and Treatment of Small Submucous Fibromyomata of the Uterus.—Dr. Byrne having taken the chair, the PRESIDENT said:—So long as the rule was generally accepted that in every case of severe uterine hæmorrhage not connected with existing pregnancy the cervix should be dilated, and the cavities explored with the finger, the diagnosis of these tumours presented no difficulty; but since the introduction of the curette has rendered this painful and somewhat dangerous preliminary in the larger number of cases superfluous, it becomes of much interest to ascertain whether these new growths can be diagnosed without previous dilatation. Four cases were detailed, showing that this was the case. The necessity for dilatation was indicated partly by the condition of the cervix, partly by feeling the new growths by sound or curette. In his opinion, dilatation of the cervix uteri was necessary only in order to remove small tumours, polypi, or portions of retained ovum. Large tumours should not be removed per vaginam, and hæmorrhage alone was not an indication. The method of dilatation which he now adopts is to commence with iodoform gauxe, and, if necessary, complete the process with Hegar's dilators. The iodoform gauze is easily employed, and may be left *in situ* for three or four days, and is, therefore, especially adapted to the wants of the busy practitioner. In all the cases the tumours were removed by means of Schultze's spoon forceps. With this instrument diseased tissue alone is attacked, and with ordinary care no harm can be done; enucleation, on the other hand, is much more dangerous and difficult. —Dr. J. BYRNE said the great difficulty was to dilate the external os, and after that had been done there was as great difficulty in dilating the internal os. Iodoform gauze was a great improvement as a gynæcological appliance for the purpose.

BRITISH LARYNGOLOGICAL AND RHINOLOGICAL ASSOCIATION, June 26th, 1889 (Sir Morell Mackenzie, president, in the chair). **Epithelioma (?) of Larynx in a Girl.**—Mr. LENNOX BROWNE showed some microscopical sections taken from the larynx of a young lady of eighteen years of age, who was supposed to be suffering from epithelioma. She had at first been thought to be suffering from laryngeal phthisis, but there were no other symptoms, and the condition had improved under treatment. The epiglottis was affected, and the left vocal cord was quite hidden from view by an ulcerated and granulating growth on the left ventricular band. Small fragments of the tissues were submitted to two pathologists of eminence, who both declared the growth to be of an epithelial nature. Swallowing, and consequently nutrition, had not been affected, and as a result, there had been but slight loss of weight; but notwithstanding the microscopical appearance, he was still uncertain as to the real nature of the case.

The PRESIDENT pointed out that it was quite unknown for a patient suffering from epithelioma to go on for two years without losing weight, as was the case with this patient.

Diseases of the Glandular Structures of the Pharynx and Naso-Pharynx.—The discussion on this subject was opened by a paper by Mr. MARK HOVELL, who dealt with the relation of follicular to parenchymatous tonsillitis. He pointed out that in most cases there must be some special cause which determined the particular form of the inflammation. One fact which seemed to bear upon this was the peculiar tendency for either form of the disease to occur, in hospital practice, in groups, the prevailing form being at one time the follicular, and at others the parenchymatous form. This tendency, he observed, could hardly be attributed to atmospheric influence. He also asked why these affections only occurred on one side, or were more severe on one side than the other. He then discussed the relationship of throat affections, especially granular pharyngitis, with uterine or ovarian troubles. On the whole, he was inclined to believe that no real relationship existed, the throat affections being merely secondary to deranged health. The question, however, still remained as to why granular pharyngitis should so frequently be found associated with ill-health in adults, and why particular deposits of adenoid tissue should be affected to the exclusion of others apparently more accessible to the effects of local change. With reference to the treatment of adenoid growths generally, he urged they should be removed whenever they give rise to ill effects irrespective of the age of the patient. Small growths might be got away with the nail, but in most cases a cutting instrument was preferable, avoiding a too extended position of the neck. A general anæsthetic was to be preferred to cocaine. He called attention to a finger guard composed of a piece of rubber tubing, which was simple and efficient.

Dr. WRIGHT WILSON read a paper on the same subject. He alluded to the vagueness of the symptoms of the presence of adenoid growths, as described by aural surgeons. In 235 cases of this kind which had passed through his hands, 225 were ordinary cases, occurring in about equal proportion in both sexes; in the remainder, deafness was the only symptom. In one there was a mastoid abscess. He pointed out the importance of exploring the naso-pharynx in every case of deafness. In ten of his cases the growths were at the sides or back of the pharynx, instead of springing from the vault, as is most usual. He explores the cavity with the index finger, pushing the lip between the molar teeth to prevent the child biting, and then, if necessary, at once introduces the forceps, repeating the process if necessary. He then leaves the patient lying on the sofa for half an hour, with instructions to call him if there should be any bleeding. All forms of exercise are forbidden for the rest of the day. Neglect of this precaution led in one or two cases to serious hæmorrhage. Of the 235 cases seen by him in 1886, 31 per cent. had concurrent disease of the middle ear. In rather more than 11.5 per cent. both tonsils were enlarged, and in about the same proportion only one tonsil was enlarged. In hospital practice, of 519 cases applying for disease of middle ear and nasal obstruction, 235 (45 per cent.) had post-nasal growths.

Dr. WARDEN said he too had noticed the curious association of certain forms of throat disease with disorders of the reproductive organs in females, but he surmised that in many instances the immediate cause of the throat mischief was depraved health. He advocated the removal of adenoid growths so soon as they came under observation.

Mr. LENNOX BROWNE objected to the term follicular tonsillitis, seeing that the crypts or lacunæ were primarily affected. He had some years since suggested that instead of follicular, they should call it cryptic or lacunar tonsillitis. He pointed out that bilateral tonsillitis was usually due to unsanitary conditions, whereas the one-sided and alternating form was associated with climatic changes, or was the result of a diathesis. With respect to the alleged association of throat disease with disorders of the generative organs, he said some of it was quite new to him, though it was twelve years ago since he had drawn attention to the association of menstrual disturbance and ozæna, and he quoted a paper, written in 1883, by Dr. Mackenzie, of Baltimore, on "The Relationship of Diseases of the Sexual Organs to Intra-Nasal Disease." He called attention to the connection between diseases of the thyroid body and glandular diseases of the larynx, and especially to catarrh of the pharyngeal bursa. The subject of adenoid growths he considered nearly thrashed out. He always operated by the finger nail, and never had serious hæmorrhage, but he entirely agreed with the precautions urged by Dr. Wilson.

Dr. HODGKINSON advocated removing the growths at different sittings, and described an instrument which he had devised for the purpose of permitting the operation to ascertain beforehand what he was going to remove.

Dr. GEORGE STOKER advocated the removal of the growths so soon as discovered, whether at four weeks, or even four days. He thought that scraping was an unsatisfactory method of dealing with the growths, and he was in favour of immediate removal under an anæsthetic. He said that he had always been enabled to control the hæmorrhage by means of a solution of tannic acid.

Mr. BOND mentioned several cases of inflammation of the pharyngeal bursa which he had met with, and asked whether they were common? He said that the subjects of hereditary syphilis seemed to be more liable than others to these growths, and then there was a marked tendency to recurrence.

Dr. FARQUHAR MATHESON said that convulsions in children were often due to the irritation set up by the presence of adenoid growths in the post-nasal region. He advocated their removal by means of the finger nail, which method, he said, was particularly useful in cases in which hearing was affected, because no instrument could be got round the angle. He thought that cocaine was often worse than useless. But he thought it was cruel to operate without an anæsthetic.

The PRESIDENT expressed a doubt as to whether there was any real connection between uterine disease and affections of the throat.

Mr. HOVELL, in reply, said he thought it was unnecessary to remove the growths unless they gave rise to inconvenience. He pointed out that the position of the growth had nothing to do with the causation of the deafness, which was due to congestion or excessive secretion.

Discussion on "Gouty Sore Throat."—Sir MORELL MACKENZIE commenced by saying that in the vast majority of cases of throat disease which were sent to him as of gouty origin were in reality nothing of the kind. He said he was only prepared to admit the influence of gout—1. When an acute throat affection suddenly disappeared upon the supervention of well-marked gouty manifestations elsewhere. 2. Obstinate affections of the throat in persons who were manifestly gouty, and those cases in which local treatment directed to the throat had failed to afford relief, but which yielded to constitutional treatment

for gout. He related a case of acute œdema of the uvula in a man, æt. forty-seven, which disappeared upon the sudden development of gouty inflammation in the big toe. The patient said he had caught cold. The uvula was the shape and size of a muscatel grape, and it appeared necessary to puncture or amputate it. By the following day, however, the swelling had disappeared coincident with the development of gout in the toe. Case 2 was that of a gentleman, æt. fifty, who suffered from a chronic affection of the throat, which had resisted all kinds of treatment. He was the subject of gouty enlargement of several joints of the fingers. He found great relaxation and elongation of the uvula, and swelling and marked congestion of the posterior pillar of the fauces. The pharynx and larynx were fairly healthy. No relief was afforded by local treatment, and ultimately the uvula was removed. Still no great benefit was derived. He then turned his attention to the treatment of the gouty condition, and gave him colchicum, purgatives, and alkalies, and at the end of six weeks the congestion of the throat had entirely disappeared. Case 3 was that of a lady, æt. forty-one, with a strong family history of gout, though the only evidence in her person was a slight deposit in the lobe of the left ear. The pharynx was found to be somewhat congested, and there was irregular enlargement of the capitula Santorini and sub-adjacent tissues on both sides. The voice was weak. Both the ventricular bands were red, and they did not meet on attempted phonation. A rounded projection could be seen on the cartilaginous portion of the right vocal cord. This enlargement was touched with the galvanic cautery, and attempts made to remove it, but they failed. In this case constitutional treatment also failed to afford relief. Case 4 was that of a gentleman who complained of hoarseness and slight dyspnœa. There was an angry-looking outgrowth on the left ventricular band, which, later on, ulcerated. It soon became deeply excavated, and inspired great apprehension. The patient subsequently went to Paris and consulted Dr. Krishaber, who unhesitatingly pronounced it to be a case of cancer. The propriety of extirpation of the larynx was discussed, but in the meantime the patient consulted Prof. Von Langenbeck, who dissuaded him from having any operation performed on the ground of the risk and uncertainty involved. He then went to Wiesbaden in order to improve the general health, and within ten days he manifestly improved, and in three weeks he was completely cured. An examination of the larynx on his return proved the absence of anything abnormal.

Dr. Dundas Grant agreed that cases of gouty sore throat were rare, but he mentioned several cases in which he had observed its occurrence. He pointed out that it added another difficulty to diagnosis in cases of suspected cancer of the throat.

Dr. George Stoker related the case of a gentleman, who had consulted him complaining of chronic irritation of the throat. The patient had lived for many years in India, and had suffered from gouty cystitis. From time to time he had brought up a little blood, which alarmed him very much. On examination, he found the larynx fairly healthy down to the vocal cords, but below that level there was a thickening or protrusion of the mucous membrane, which was smooth, and occupied about a third of the lumen of the tube. Notwithstanding a history of syphilis when young, iodide of potassium and mercury did not bring about any improvement in the condition, and he was obliged to diagnose between gout and cancer. The patient had another severe attack of hæmorrhage, but the growth did not increase in size, and the body weight was maintained. The patient had been seen in the interim by an eminent laryngoloist, and he had been pronounced to be suffering from cancer. He had omitted to mention that the thyroid was the seat of an indolent goître. It was not possible to remove any portion of the growth for microscopical examination; but he was still inclined to regard it as due to gout, and not cancer, especially as in the interval he had consulted Dr. Garrod, who had prescribed an anti-gouty treatment.

Mr. Millican mentioned two cases in which the throat symptoms had yielded to salicylate of lithium. He endorsed the remark by Dr. Stoker as to the necessity for distinguishing clearly between a gouty sore throat and a sore throat in a gouty person.

Mr. M. Hunt read a paper on **Lupus of the Throat and Nose,** pointing out the difficulty of diagnosing this condition, which, although rare, was still met with in a certain number of instances.

The President said it was quite exceptional for such cases to come under his notice, and they were rarely met with unless specially searched for in the practice of skin specialists.

Dr. Hodgkinson mentioned a case in which obstinate ulceration of the lower lip was suspected to be lupus, but turned out to be tubercular.

Dr. Dundas Grant alluded to the very excellent paper on the subject by Mr. Lennox Browne, and mentioned two cases which had recently come under his notice in the diagnosis of which he had been very greatly assisted by the information therein contained. He pointed out that tolerance of manipulation was a sign of great diagnostic value. He effected a cure in one instance by thoroughly scraping the ulcerated surface and daily applying a 60 per cent. solution of lactic acid. He remarked that he had recently had occasion to examine the larynx of two lepers in whom the appearances strikingly resembled those of lupus.

Professor Collier demonstrated by dissections and diagrams the existence of a hyo-epiglottic membrane.

Surgical Aids and Appliances.

126.—THE J R P INSUFFLATOR.

Mr. John R. Philpots, L.R.C.P. & S. Ed., J.P., etc., has devised an instrument for use in the insufflation of suitable powders, in the early stages of nasal catarrh and hay fever, the accompanying sketch of which shows the design. It has the following important advantages: (1) It is

small, and light enough to be carried in the waistcoat pocket. (2) Being kept charged with powder, the prompt application which is so necessary can be secured. (3) If the lid of the powder chamber is properly screwed, the contents cannot escape into the pocket or become damp. The following is the mode of preparation and application: Fill the inverted lid of box with the powder, and screw it upwards into the body of the box moderately tight. When required for use, turn the lid so as to bring the niches on its edge in line with the tube. Place the nozzle by turns in each nostril, and give a sharp puff through the mouthpiece. Screw the lid tightly "home" after each insufflation. The box should be re-charged after the third or fourth application, to ensure a sufficient supply being always on hand. In nasal catarrh, the application should be as immediate as possible, before a second sneeze, if practicable. The inconvenience may be temporarily increased thereby, and a slight tingling will be produced; but this will soon pass off, and the beneficial results become manifest in the prevention of the development of the cold. The ordinary Dover's powder will be found very effectual; but, of course, any speciality can be used. At the approach of the hay fever season, those who suffer from this trying complaint will do well to use this instrument for the application of the powder (formula as given below) before leaving the bedroom in the morning, and again before going into the open air. Formula—Sodæ salicylas, ℈iv.; acid boracic (pulv.), ʒj.; cocaine hydrochlor., grs. 22. Also the following has been found useful: Salol; acid boracic (pulv.)—partes equales. It is absolutely necessary that these powders should be mixed by being shaken together in a large wide-mouthed bottle, rather than being pounded, which causes them to cake. It is, of course, understood that insufflation forms only part of the treatment of hay fever—the constitutional remedies will depend upon the peculiar idiosyncrasy of the sufferer.

Medical Miscellanea.

The subject of our next illustration will be Sir William Aitkin.

* * * *

Sir James Crichton Browne has been appointed treasurer of the Royal Society.

* * * *

Professor Virchow, Drs. von Bergmann and Waldeyer, have been entrusted with the preliminary organisation of the next International Medical Congress, to be held at Berlin August 6th, 1890.

* * * *

The University of Oxford has conferred the honorary degree of D.C.L. on Dr. John Billings, so well known by his literary labours on the "Index Medicus," and the "Index of the Surgeon-General's Library of the Army Medical Department." Dr. Billings is attached to the American Army in the capacity of surgeon.

* * * *

Dr. Malet, Medical Officer of Health for Wolverhampton, has on the occasion of his approaching marriage, been presented by the members of the Sanitary Committee of the Wolverhampton Town Council with a very handsome Chippendale arm chair, as a mark of their appreciation, and in token of their good wishes.

Dr. Michael Calleen has been appointed a justice of the peace for the county of Louth.

* * * *

The new Jubilee College Hospital for Epsom and Ewell, which has been erected at a cost of £1,700, was opened the middle of July by the Duchess of Teck.

* * * *

The death is announced at Cheltenham of Deputy Surgeon-General Francis Day, F.R.S., LL.D., on July 10th. He was a distinguished officer and naturalist.

* * * *

The Lord Chancellor has placed the name of T. E. Brooks, M.R.C.S., on the Commission of the Peace for Ludlow. Mr. Brooks was Mayor in 1885-6.

* * * *

The Directors of the Assistance Publique have distributed among the infirmiers and infirmierès of the Paris Hospitals 2,000 tickets for the Paris Exhibition.

* * * *

Dr. Whitelegge, Medical Officer for Nottingham, has been appointed Medical Officer of Health for the West Riding, at a salary of £800 per annum. There were seventy-two applicants.

* * * *

John V. Shoemaker, A.M., M.D., and John Aulde, M.D., are engaged on a "Treatise on Materia Medica, Pharmacology, and Therapeutics, which they expect to have out early in the autumn.

* * * *

An instance is reported in America of a child who found its mother's pill box with one hundred pellets of quinine and strychnine, and straightway ate thirty or forty of them under a false impression. The coroner held the usual inquest.

* * * *

For the vacant post to the Queen's Hospital, Birmingham, there are several candidates. There appears to be some doubt whether the appointment will be a purely medical one, or whether the officer will be a gynæcologist as well as a physician.

* * * *

The annual examination for scholarships at Epsom College has resulted in the following elections. Seniors: H. Boulton, A. C. Knight. Juniors: T. Chelwood, F. D. Crosthwaite. Entrance £40: S. M. Smith, from Mr. Tomkins, Yarmouth. Entrance £20: E. E. Child, from Cranligh School. Prize of £10: T. Pritchard (to be raised to £20 scholarship conditionally another year).

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the EDITOR, "*The Provincial Medical Journal*," *Horton House, Halifax.*

Matters of business should be addressed to the Publisher, at the Offices, 10, *Friar Lane, Leicester.*

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked.

Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16*th of the month.*

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

A PUBLIC PROSECUTOR.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—Would it not be possible to have a public prosecutor, as is done in Canada. I enclose a cutting from a Toronto journal, showing how they deal with unlicensed practitioners. At the meeting of the Ontario Medical Council, June 12th, 1889, the prosecutor presented his report. A detailed statement of the past year's work was given. The number of prosecutions under the Ontario Medical Act amounted last year to thirty-four, the fines reaching the sum of $1,525, while an amount of $240 remains unpaid. Information being laid against a doctor in a certain northern town, he immediately left and remained away until he passed the Council examination, when instructions were given to stay proceedings. The charge against a magnetic practitioner of London was dismissed by the magistrate on the ground that it was not practising medicine when no medicine was used. At the request of some registered practitioners the prosecutor had notified some five women to cease violating the Act, or they would be fined, and it was noted that all the women meekly obeyed. It was moved by Dr. Philip, seconded by Dr. Ruttan, "That Mr. W. W. Webb be re-appointed as prosecutor for the Medical Council upon the same terms and conditions as last year." The motion was carried. The Council then resolved itself into Committee of the Whole to discuss a number of reports, which will be further dealt with to-day.

By having a public prosecutor, the onus of prosecution is removed; the prosecutor's interest would be to look up cases, and thus protect the profession.—Yours truly, M.D.

THE BINIODIDE OF MERCURY.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

DEAR SIR,—The immense superiority of the biniodide as a germicide has this year been experimentally proved, as you are probably aware, by Dr. Woodhead, of Edinburgh. Permit me, as the first practitioner to point out its value in the treatment of scarlet fever and diphtheria, to submit to your notice some important uses of the drug other than those described in my work upon "The Treatment of Specific Febrile Disorders," and to describe methods of prescribing it in other diseases, for the purpose of showing that it possesses other curative properties of a high order. I wish most particularly to call your attention to the fact that such is the penetrating power of the iodide of sodium vehicle, that ophthalmia neonatorum may be cured in four or five days with the biniodide in sodic iodide, of the strength of 1 in 3,000, and ringworm with one application of a 1 in 4 solution.

I. *Local Uses.*—Precipitated and re-dissolved by adding a solution of sodic iodide (1 in 4) to sol. hyd. bichlor. (B.P.). Thus sol. hyd. bi. ℥viii. Sol. sodii iodidi (1 in 4) ℥j. Mix, and thus prepare a 1 in 1,000 solution. Dilute with ordinary water for the various strengths required. Thus for disinfectant uses as a spray, it may be used pure; surgical dressing, 1 in 2,000; otorrhœa, 1 in 2,000 or 2,500; ophthalmia neonatorum, 1 in 3,000; alopecia areata, 1 in 500 (by preparing the sol. hyd. bichlor. of double strength, 1-500); scabies, 1 in 500; puerperal septicæmia, an injection of 1 in 2,000 (warm); scarlet fever and diphtheria, a spray of 1 in 2,000, frequently (scented if for children); ozœna, 1 in 4,000 or 5,000 (warm); hay asthma, 1 in 2,000 as inhalation spray and douche (warm); gonorrhœa, 1 in 4,000 to 5,000, with aqueous solution of opium. Then also in the form of a strong solution of various strengths—thus: to ℥ss. hyd. biniodid. add ℥ss. sol. sodii iodidi, and a strong blistering fluid of full strength is prepared; for the cure of ringworm, add three parts of water to a small quantity of this strong solution, and apply once with a camel's-hair pencil; for epulis, inject one or two minims of the 1 in 4 into the base of the tumour once a week (after cocaine) until cured, for rodent ulcer of the face, apply the strong solution to the raw surface twice a week for three weeks, and then allow to heal, applying zinc ointment for that purpose; for poisoned wounds, apply the 1 in 4 solution daily until the local symptoms subside, and give iron internally.

II. *Internal Uses.*—In mixture, pill or powder (with sugar). Mixture: sol. hyd. bichlor. ℥i.—℥iss.; potass. vel. sodii iodid. ℥ss.; syrup. aurant. vel. aq. menth. pip. ad. ℥vi. Dose, one tablespoonful every two, three, or four hours. Pills, $\frac{1}{16}$th to $\frac{1}{4}$th grain. Powders, with two grains sugar to every $\frac{1}{16}$th grain of biniodide. In meningitis, mixture every two or three hours; pleuritis the same, with chloral or morphia as sedative for cough, and blisters externally; neuralgia, mixture with chloral and bromide, five to ten grains of each; acute congestive headache, with quick pulse and flushed face, pill of $\frac{1}{4}$ grain every four hours, or mixture every two hours; chronic headache, the same three times a day, with double doses of sodic iodide; ñatulent

dyspepsia, with constipation and disordered liver, pills ¼ grain, one at bedtime; cholera, preventive and curative, $\frac{1}{16}$th grain to ⅛th three times a day, with brandy and ammonia; alopecia areata, to check and destroy, mixture three times a day; gout, mixture every two or three hours, with chloral and bromide, if sleepless; iritis, every three or four hours; interstitial corneitis, mixture *ter die*; chronic skin eruptions, mixture; amenorrhœa, in pill with ammonia, and ammonio-citrate of iron in mixture; in sleeplessness from chronic alcoholism or heart disease, in pill (gr. ¼) every four hours. From the curative action in epulis, I should think the biniodide would prove of singular service in the destruction of cancers, and other malignant growths, by injection into their substance.—Believe me, Sir, yours faithfully,

C. R. ILLINGWORTH, M.D.

P.S.—In puerperal septicæmia, I give the biniodide in pill (gr. ¼) three times a day, besides using it locally.

REJUVENESCENCE.

To the Editor of The Provincial Medical Journal.

Sir,—Oliver Goldsmith in one of his essays writes thus: "The improvements we make in mental requirements only render us each day more sensible of the defects of our constitution; with this view, therefore, let us often recur to *the amusements of youth;* endeavour to forget *age* and wisdom, and as far as innocence goes, *to be as much a boy* as the best of them. The character of old Falstaff, even with all his faults, gives me more consolation than the most studied efforts of wisdom I have: behold an agreeable old fellow forgetting age, and showing me the way to be *young* at sixty-five. Sure I am as well able to be merry, though not so comical as *he*. It is not in my power to have, though so much wit, at least as much vivacity. Age, care, wisdom, reflection, begone! I give you to the winds! Let's have t'other bottle. Shakspear, here's to you and Falstaff, and all the merry men of Eastcheap." Another Oliver—Oliver Wendell Holmes—took a joyous flight into, and between, the brackets of "Life's roseate parenthesis," and enjoys a second youth at seventy-nine. Brown-Sequard tells the Biological Society of Paris that, albeit seventy-four, "I have now returned to my twentieth year." Well, in the cases of the two Olivers, we know 'twas the force of a vivid imagination which brought them into this happy state of rejuvenescence. Brown-Sequard ignores all idea of imagination. The *modus operandi* in Brown-Sequard's case in achieving this rejuvenescence is quite a startling revelation! He does not tell his audience *who saw* him at his first operation, nor *who saw* him expressing from the ablated organs the fluid, nor *who saw* him hypodermically injecting that fluid into his thighs for fifteen days, one injection per diem. Again, he does not explain how the foreign semen got into his own testicles after these injections, which gave him, he says, all the vigour of a young man of twenty! I would ask him if he had impregnated a young female at the moment of this wonderful transformation, would her offspring be a pup, or a kitten, or a calf, according to the animal castrated, or if in his own testicles the foreign fluid was to undergo a phenomenal change into a fluid full only of *human spermatozoa*. It is very probable that his contemporary, Septuagemius, would be rather nervous in these hypodermic operations, fearing that nothing short of blood-poisoning would be the sad result. I would say that his announcement is to me a wild, unreasonable, incomprehensible *dream*——of *dotage*.—Yours obediently,

Kanturk, Co. Cork,
July 22nd, 1889.

A MONTHLY REVIEW OF MEDICAL SCIENCE, LITERATURE, AND BIOGRAPHY.

VOL. VIII.] SEPTEMBER 2, 1889. [No. 93.

Our Portrait Gallery.

SIR WILLIAM AITKEN.

SIR WILLIAM AITKEN was born in Dundee, Forfarshire, Scotland, on April 23rd, 1825, and educated at the high school there. After serving an apprenticeship to his father, a surgeon in Dundee (who was also surgeon to the Dundee Prison and to the Dispensary), he attended the Dispensary and the Dundee Infirmary as a dresser and clinical clerk, and later on as a resident medical officer for a short time. He matriculated as a student in the University of Edinburgh in 1842, attending first the art classes, subsequently passing through the medical curriculum, and proceeding to the degree of M.D. in 1848, and the same year obtaining the license of the Royal College of Surgeons in Edinburgh.

Dr. Aitken obtained the following prizes and honours in the classes of arts and medicine in the University of Edinburgh: In 1842-43, prize in Junior Mathematical Class, and prize for essay. 1843-44—Hon. certificate in Advanced Mathematical Class. 1846-47—Prize in Botanical Class. 1846—Prize in Faculty of Medicine for essay on a scientific subject, given by the students of the four faculties, and decided upon by a committee of professors; honorary certificate in the class of Physiology; highest prize in Surgery, and gold medal for Surgery. 1848—Gold medal for dissertation on taking degree of M.D. in University of Edinburgh.

In the same year he became Demonstrator of Anatomy in the University of Glasgow, and continued to hold that office, and that of Pathologist to the Glasgow Infirmary, till April, 1855. After the Crimean War, he was appointed on January 28th, and gazetted March 27th, 1860, as Professor of Pathology in the Army Medical School. In 1873 he was elected a Fellow of the Royal Society; and in 1881 a member of the Athenæum Club. In 1887 Dr. Aitken had the honour of knighthood conferred on him, on the occasion of the Queen's Jubilee. In 1888 he had the degree of LL.D. (*honoris causa*) conferred by the Universities of Edinburgh and Glasgow. He also has had the honour of election as a Corresponding Member of several foreign medical societies.

Sir William is the author of numerous papers on pathology and the science of medicine, of which the following may be mentioned: (1) "On Inflammatory Effusions into the Substance of the Lungs, as modified by Contagious Fevers," 1849. (2) "Contributions to Pathology." (3) "On the Pathology of the Diseases of the Troops in the East during the Russian War, 1855-56," in conjunction with Dr. R. D. Lyons. (4) "On the Diseases of the Troops in the East during the Russian War, and on the Climate of Scutari on the Bosphorus," 1857. (5) "Medical History of War with Russia," 1857. (6) "On the Persistent and Pernicious Influence of Residence in Bulgaria on the subsequent health of the British Troops in the Crimea." (7) "On conducting *Post-mortem* Examinations at Coroners' Inquests," 1857. (8, 9, 10) "On the Pathological Connexions and Relations of Epidemic Diseases in Man and the Lower Animals, with special reference to the relationship between the health of man and the condition of his food," 1857. (11) "Analytical Review of the Transactions of the Medico-Chirurgical Society of London, vol. xii.," 1859. (12) "Critical and Analytical Review of recent works on the Pathology of Vaccination, and its protective influence from Small-pox," 1857. (13) "Analytical and Critical Review of the first Decennium of the Pathological Society of London," 1858. (14) Handbook of the Science and Practice of Medicine," 1858 [this has now reached its seventh edition.] (15) "On the Growth of the Recruit and the Young Soldier," now in its second edition. (16) "On the Doctrine of Evolution in its Application to Pathology," 1885-86. (17) "On the Animal Alkaloids."

The portrait is taken from a photograph by Mr. A. J. Melhuish, of 12, Old Bond-street, London, which was enlarged by order of the Council for the British Museum of Portraits, South Kensington.

Original Communications.

SUSPENSION IN THE TREATMENT OF AFFECTIONS OF THE SPINAL CORD.[1]

By Alexander B. Shaw, M.D.,

Professor of Diseases of the Mind and Nervous System and Electro-Therapeutics, Beaumont Medical College; Consulting Neurologist, St. Louis Insane Asylum, Alexian Brothers' Hospital, St. Louis Railroad Hospital, etc.

Suspension in cord affections occurring secondarily to disease of the vertebræ was advocated, and practised with good results, so long ago as 1826, by Professor J. K. Mitchell, of the Jefferson Medical College, and has been employed for a number of years by Dr. S. Weir Mitchell[2] in the same class of cases. The latter, indeed, about the time of Motchoukowsky's discovery, was induced to attempt suspension in two cases of spastic paraplegia in which no spinal caries existed; the excellent results obtained from it in pressure paralysis having led him to believe that stretching the cord, and thus altering its vascular conditions, even when signs of meningeal inflammation were absent, would helpfully affect both cord and membranes. Unfortunately, in these cases, no benefit followed; had it been otherwise, suspension would, no doubt, long since have been generally recognised as a useful adjunct to our scanty therapy in chronic degenerations of the spinal cord.

The fact that suspension is beneficial in the treatment of locomotor ataxia was discovered by Dr. Motchoukowsky, a Russian physician, in 1883, while treating a patient for spinal curvature, who was then suffering from ataxic symptoms. He observed that amelioration of the ataxia followed the suspensions made during the applications of the plaster jacket used for the relief of the curvature, and subsequently suspended other ataxic patients with like favourable results. This important discovery was chronicled and published in a *brochure* on the subject by Dr. Motchoukowsky, in 1883, in which considerable improvement was scribed to it in twelve tabetic persons; also in various neurasthenias, independent of tabes, in which the sexual functions were re-established by this treatment. But, until quite recently, it has been almost barren of results.

However, on the 15th of last January, Professor Charcot, of Paris, delivered a clinical lecture at the Salpétrière, in which he stated that he had recently been experimenting with the suspension treatment of locomotor ataxia, and had been obtaining very remarkable results. Charcot's lecture was published in *Le Progrès Médical*, January 19th and February 23rd, 1889, in which is graphically described the technical details of suspension, as practised by him, with an ordinary Sayre's suspension apparatus. After describing the apparatus, he lays great stress on the danger of causing unpleasant head symptoms, from compression of the blood-vessels in the neck, if the straps are not properly adjusted. Further on, he says: "When the head is duly disposed of,[3] the shoulder-pieces are slipped under the armpits. Though they may appear of minor importance, they really play the part of regulators during the period of suspension. *For*[4] *it is necessary that, whilst lifted off the ground, the patient should not be entirely supported by the head-piece, for then the traction would become, in some cases at least, absolutely intolerable.* . . . . Careful trials are necessary to determine the exact length of the several straps. . . . . While suspended, the patient is made, at intervals of fifteen or twenty seconds, to raise the arms laterally away from the body, so as to transfer more weight upon the head-piece, and so render the traction upon the elongation of the vertebral column still more complete—as complete as is tolerated by each individual. . . . . As a rule, the longest time of suspension must not go beyond four minutes, three minutes being taken as the average. Half of a minute is enough at the outset, the maximum being reached during the first six or eight applications of treatment. It is essential to take into account certain individual susceptibilities or physical peculiarities, among which stands foremost the body weight, for, while a person of from about 130 to 150 pounds may be suspended forthwith during two minutes or more, the case is quite different in those whose weight reaches 180 pounds or more. In the latter, the tension to which the structures of the neck are subjected may become very severe and painful, and be felt sometimes for a whole day afterwards. . . . It is well to note that certain patients have such a wish—a very natural wish—to get better, that they think themselves bound to stand any amount of pain without complaining; but this circumstance is positively detrimental to the success of treatment, which must be accompanied with but trifling discomfort, at the most, without real pain or fatigue, lest it should defeat its own ends. . . . . Suspension must not be carried out oftener than once on alternate days, otherwise it may become more hurtful than beneficial. . . . . When the full time has elapsed, the operator very gradually lets the rope loose, so as to avoid *every trace*[5] *of jerking* during the descent. The patient is to be supported while being freed from the apparatus, and made to rest awhile in an arm-chair, brought near for the purpose."

Up to April 1st, Charcot reports over 800 suspensions, with varying degrees of success, but, in the vast majority, walking is improved after the first suspension.[6] At first, this improvement lasts but a few hours, but after eight or ten *séances* it persists. After twenty or thirty treatments Romberg's sign disappears. Then vesical troubles are lessened or removed, also the lightning pains. Sexual impotence gives place to sexual desires and erections. (Experiments by Dr. Onanoff on healthy persons have shown that this method has an exaggerating effect on virility). The cotton-wool feeling in the feet gives way, more or less, to healthy sensations, and, in general the whole health improves. Every patient steadily improved, with one exception—a young tabetic of thirty-two, who at first improved, then fell off, then improved somewhat. But the knee-jerks have not reappeared in any of the patients, after three months' treatment, nor are the pupillary symptoms altered. As to other diseases, a young female with Friedreich's disease was greatly improved by the treatment. In neurasthenic and impotent patients, the sexual functions were re-established.

Suspension has also proven beneficial "in[7] Parkinson's disease (paralysis agitans), the rigidity and stiffness having given way to a great degree, the sensations of *chaleur* (flushings) have abated, the sleep is improved, and the

gait has become less fatiguing. The tremour, however, remains as persistent as ever."

April 15th, 1889.—Bernhardt[8] reported to the Berlin Society for Mental and Nervous Diseases the result of 219 suspensions made in nineteen cases. No unfavourable symptoms observed. Several patients complained of pain in nuchal muscles. Frequency of pulse unchanged. Traumatic paralysis not observed. In certain cases *decided* improvement occurred in different ways.

Lacinating pains were relieved.
Patients can walk firmer and longer.
Urinating is improved.
Sleep is better.
Don't fall out of bed any more.
Sexual power has been regained.
Many say they feel better, stronger.

Suspension is harmless yet potent to benefit certain symptoms. The mental influence is to be considered. The therapeutic *modus operandi* is as yet undetermined. The physician should always superintend suspension. Great care is necessary in cases suffering from heart affections. Eulenberg states that he and Mendel obtained similiar results, forty cases being treated from February 3rd to May 10th, 1889; thirty-one were men and nine women. One case of pseudo tabes (woman) hysteria. Marked improvement.

One case of chron. myelitis (woman). No improvement. Three cases of paralysis agitans. One withdrew from treatment. One no improvement. One walking better. Muscular spasm in arm relieved. One case, traumatic neurosis (man). No improvement. Thirty-four cases of tabes. Several cases had sixty suspensions. Some were suspended daily. Of these five withdrew from treatment, six were discharged unrelieved, two were relieved, one after thirty-nine and the other after sixty suspensions. Still under treatment, twenty-one. Of these four were markedly improved, twelve somewhat relieved and five not affected. In one case syncope occurred at the commencement of treatment. This is the only case in which an unfavourable effect was observed.

In referring to the treatment of locomotor ataxia and transverse myelitis by suspension, in a clinical lecture delivered at the New York Post-Graduate Medical College, Dr. Chas. L. Dana, Professor of Nervous and Mental Diseases, says: The patient I show you here is the ninth case of locomotor ataxia which I have submitted to this treatment in the past two months. Of these, four have had from twelve to sixteen suspensions, and of the five, three report decided improvement in the gait and in sensory troubles. I have also employed the treatment in four cases of transverse myelitis. One discontinued treatment after a few trials, and I think it hurt him; two have just been treated only a short time; one has been remarkably benefited, as regards strength in the legs and greater freedom of movement. In certain cases, not recent, of dorsal myelitis in the middle or upper dorsal region, the suspension will, I think, be of much service. But it must be employed carefully. The patients are suspended with about equal support to the head and under the head and under the shoulders. After a time, more weight may be thrown on the head. Dr. R. M. Simpson, of Winnipeg, Canada, reports[9] two cases of tabes as materially benefited by suspension. Edward Waitzfelder, M.D.,[10] Neurologist to the Randall's Island Hospital, New York, says: I began the suspension treatment in the nervous ward of the Randall's Island Hospital with but little hope of benefit and more from a sense of duty to the unfortunate patients than from any expectation of doing good. The patient was raised just far enough to let the tips of the toes touch the ground. In some of the cases the loops were put under the axilla; in others they were left off.

Case I. –M. O'S——, æt. thirty-nine. History of ataxia for three years. No pains since treatment began. Gait improved. Patient says he feels stronger. After twenty-four suspensions, gait very much improved. Ataxia in walking markedly diminished. Can walk almost in a straight line with eyes closed.

Case II.—æt. thirty-eight. Cerebellar hæmorrhage (?). No objective improvement.

Case III.—J. D——, æt. sixty-three. History for eight years. After fifteen suspensions can stand for short time when eyes are closed; gait very much improved; can now walk without a cane; numbness of feet diminished. The feet, which were always cold before, are now warm. Can pass urine easier than before. No improvement in pains after twenty-four suspensions. Patient thinks they are more frequent and severe than before treatment. Gait very much improved; formerly walked with a marked ataxia of feet, bringing down the heel with a severe shock. Now the walk is very slightly characteristic and the "stamp" of the heel very little and would hardly be noticed. Subjective increase of strength in lower extremities and back. Cramps in legs, which were frequent before, have entirely left him.

Case IV.—æt. fifty-six. History for nine years. After fifteen suspensions, much improved in general condition, walks better; legs feel stronger. Has had no pains at all since suspension was commenced. Urinates with less difficulty, and bladder less irritable. Gait much improved, but little "stamp" to the heel. "Can walk a mile now with as little fatigue as a quarter of a mile before."

Case V.—A. C——, æt. fifty-one. History for three years. Until four days before suspension was commenced, patient was confined to bed for over eight months on account of extreme ataxia of feet and legs. After sixteen suspensions his gait is fairly good, though it still shows inco-ordination; he can follow a straight line for a short distance, can start walking and stop abruptly without much staggering, can turn about suddenly ("right-about-face") with only a little wavering. Has not been in bed in the day-time since treatment was commenced. Diplopia almost gone; subjective increase of strength in lower extremities.

Case VI.—C.B——, æt. fifty-three. History for five years. Patient used to sit in the ward all day, very seldom moving from his chair; said he was not able to walk. After fifteen suspensions, so much improved that he insisted on having his discharge, saying he was entirely free from pain, and could walk as well as ever he could. The improvement was marked from the first suspension.

That there is a direct relation between the effect and cause in these cases there can be not doubt, and that there had been a direct impression produced on the spinal cord, but in what way I am as yet undecided. It is likely that the traction exerted on the spinal nerves in some way brings about a change in the circulation and nutrition of the cord, and the amelioration of the symptoms is due to

[8] *Centralblatt für Nervenheilkunde, Psychiatrie, etc.*, June 1st, 1889.
[9] *Canadian Practitioner*, June, 1889.
[10] *Medical News*, June 1st, 1889.

a lessening of the vascular supply of the cord and its membranes.

On May 1st, 1889, D. D. Stewart, M.D.[11] read a paper before the College of Physicians of Philadelphia reporting the treatment of fourteen cases of disease of the spinal cord by suspension, of which cases 1, 2. 3, 4, 6, 7, and 8, were locomotor ataxia (second stage). Case 5 was locomotor ataxia (first stage). Cases 9, 10, and 11 were primary spastic paraplegia. Cases 12 and 13 were combined lateral and posterior sclerosis and case 14 was one of subacute dorso-lumbar meningeo-myelitis.

He closed his papers as follows: The total number of suspensions made in these cases is upwards of 352. In the tabetics, the symptoms which were first and most strikingly relieved were the ataxia and the lancinating pains; improvement in these occurred in all, and after a very few suspensions; and that, if any relation existed between the early appearance and extent of the improvement and the duration of the disease, it is a direct one; the more chronic cases being those most promptly and decidedly benefited. The improvement in these two symptoms was so prompt and decided that it may well be considered truly remarkable.

Bladder and rectal difficulty, present in two of the tabetics, and increased sexual desire present in one, have disappeared. Diminution in, or loss of, sexual desire, present in five; has improved in but one. Tactile anæsthesia has much improved in three and slightly in one; not at all in four. A somewhat melancholic condition, present in five of the tabetics, disappeared after a few suspensions. This was not due directly to the suspensions, but was rather secondary to the lessening of the pains and ataxia. In none of the eight has the knee-jerk returned, even with reinforcement.

In the three spastic cases, diminution in the paralysis, rigidity, and spasm has been striking in one and slight in another; in the third, no change has occurred in these symptoms. In one of the ataxia paraplegic cases ataxia and paralysis seemed to be lessened after the second suspension. Unfortunately, this improvement was not maintained, possibly because suspension was not preserved in. The other case writes me that there has been marked improvement in gait and pains.

In the case of myelitis, the improvement in the paraplegia and in the general condition has been decided. It may be safely asserted, from the favourable results obtained in nearly all of the tabetic cases, that suspension is of great service in locomotor ataxia, but, whether palliative merely or actually curative, the time has not arrived for definite reply. It is certainly of use in lateral sclerosis; and, in myelitis, the decided improvement produced in one case, in which absolute paraplegia had existed for over six months, commend its trial in others. As an adjunct to other modes of treatment, its utility is beyond question. Apropos to a question quite frequently propounded to-day, we make the following extract:[12]

"HOW DOES SUSPENSION ACT IN LOCOMOTOR ATAXY?"

"1. It has been ascertained that in tabes, posterior spinal meningitis habitually accompanies the pathological changes in the nerve tubes of the posterior columns. The pia mater is found congested and thickened at the level of the posterior columns, . . . it appears to me highly probable that part of the influence of suspension, by which the spinal cord is efficiently stretched, is owing to the *breaking down of adhesions from chronic meningitis*, thus allowing a freer transmission of nervous influence along the nerve tubes. . . . The neuroglia, from being originally soft and yielding, gradually, as the disease progresses, loses its cells and nuclei, becomes firm, hard, and fibrous, and is liable to cicatricial shrinking. . . . Now it seems to me allowable to assume that by the process of stretching the spinal cord, *the overgrown and unduly hardened neuroglia may be loosened and broken down*, with the effect that those nerve tubes which have to some extent survived the sclerotic process are freed from compression, become better nourished, and may be thus enabled to transmit the nervous influence more efficiently than before. Apart from this, however, I have come to the conclusion that suspension has, in a number of cases, a beneficial influence on the medulla oblongata, as it stimulates the centres for vasomotor and cardiac action and for digestion. . . . In a large majority of my cases the appetite and digestion have improved, and mental depression has been lessened or improved.

"The forms of nervous disease for which my personal experience leads me to think that suspension is applicable are the following:—1. Locomotor ataxy in the second stage. 2. Paralysis agitans. 3. Spastic spinal paralysis. 4. Amyotrophic lateral sclerosis. 5. Functional nerve prostration, more especially where there is feeble action of the heart; loss of appetite; and severe mental depression."

The recent plausible explanation as to the action of suspension in tabes, offered by Althaus, indicates that permanent benefit may result from this method, provided that the further progress of the disease can be arrested by other means, and that it has not advanced to complete destruction of the nerve tubules; and that even where its advance cannot be thus stayed, temporary good may still be accomplished by suspension. Althaus' ingenious explanation applies equally to other degenerative diseases of the cord than tabes, and if it is true of the chronic degenerations, in which the pathological changes originate in the nerve elements and the over-growth of connective tissue is secondary, it is, theoretically, far more so of inflammatory processes which starting in the connective tissue, cause, primarily, at least far less damage to the nerve tubes. In chronic inflammations of the cord or its investing membranes which are stationary and are encountered before the contracting perineural tissue has, by compression, done more than interfere with the nutrition and conductivity of the fibres, not irreparably damaging their structure, the effect of suspension should be curative; for, by stretching the cord and the thickened and adherent membranes, the inflammatory tissue pressing upon the axis-cylinders will be loosened and broken down, setting free the latter and permitting them to resume their functions.

All of the suspensions reported by Motchowkowsky, of Odessa; Charcot, of Paris; Abedie, of Paris; Onanoff, Mendel, Barnhardt, and Eulenberg, of Berlin; Dana, of New York; Simpson, of Canada; Waitzfelder, of New York; Stewart, of Philadelphia; Althaus, of London; Saundby, of Birmingham; and others, have been made by means of the Sayre's suspension apparatus. A feeling that danger lurked in this crude mode of suspension, which is rendered a certainty by the report of a fatal result in *Le Praticien* for May, 1889, led me to contrive a suspension

[11] *Medical Record*, June 8th, 1889.
[12] Julius Althouse, M.D., *Lancet*, April 13th, 1889.

apparatus, which was made for me, and is for sale by the A. M. Leslie Surgical Instrument Company, of St. Louis.

This device secures *a*, ready adaptation and facility of application to any sized individual without changing length of straps. *b*. Completeness of control of patient. *c*. Suspension entirely by either shoulders or head, or by both conjointly and equally, or conjointly yet unequally, to any desired degree, to the fraction of a pound. *d*. Exactness as to the amount of tractile force exerted at any moment on the neck.

Its use prevents intentional as well as unconscious deception by the patient as to the amount of weight he is supporting by his head, thus placing the operator without the pale of possible mistakes. It affords an accurate basis for dosage of traction and reports of results. In short, it secures perfect precision, which is the essence of science. It will readily be seen that the scales and attached pulleys when detached afford an instrument peculiarly adapted to the accurate stretching of long peripheral nerves, and of reducing luxation; and the surgeon will discover in this invention the most perfect apparatus yet devised for suspending those suffering from spinal diseases and deformities relegated to his domain. And lastly, by removing the head strap, and shifting the ropes from the upper to the lower cross-bar, and fitting a piece of board into the loops at their lower extremity, a perfect office weighing outfit, much needed by insurance examiners, is secured.

So many perfectly reliable observers working in the interests of science and humanity present such a consension of opinion regarding the beneficial results to be obtained from suspension in certain diseases of the spinal cord, that I am convinced that benefit will accrue from its use in many cases of tabes dorsalis, Friedereich's disease, neurasthenia, impotence, paralysis agitans, transverse myelitis, spastic spinal paralysis and amyotrophic lateral spinal sclerosis. And I shall also give it a trial in chorea, disseminated sclerosis, hysteria, epilepsy, myoclonus multiplex, myotonia, monospasm, lumbago, sciatica, and other allied affections. The technique of the operation of suspension as performed by myself, and a report of the results of treatment in fifteen cases, omitted because of lack of space, will appear in the *St. Louis Medical and Surgical Journal* for August, 1889.

Note.—Since writing the above, I see in the *New York Medical Journal*, of May 11, 1889, that Dr. W. A. Hammond has introduced a spring scales into his apparatus.

A FEW PRACTICAL REMARKS ON TRUSSES AND THEIR APPLICATION TO INGUINAL AND FEMORAL HERNIÆ.

By C. B. Keetley, F.R.C.S.,

SENIOR SURGEON TO THE WEST LONDON HOSPITAL; LATE SURGEON TO THE SURGICAL AID SOCIETY.

The following paper will have, as a redeeming feature, the conspicuous merit of being on the subject of trusses and yet containing no suggestion of a new truss, or truss pad, or even so much as a new strap. I will endeavour to deal in a useful way with the application of the common kind of truss worn by the vast majority of ruptured people.

"Fit," the Most Important Quality of a Truss.—In Parkes' "Hygiene" it is said that the Duke of Wellington, being asked what was the first essential for a soldier in active service, replied "A good pair of boots." Being then asked what was the second, he reflected a short time and again replied "A good pair of boots." So, also, the first essential for a truss is *fit*, and the second essential is also *fit*. When this is wanting no excellence whatever in the material or plan of the truss will be of any value; when, on the other hand, a good fit is assured, the simplest, plainest, and cheapest of trusses will often give the highest satisfaction to both patient and surgeon.

Fitting a Patient with a Truss a very simple matter.—Now the process of fitting on a truss is usually a far simpler plan than would be inferred from the directions given in the text-books. Only one measurement, as a rule, needs to be taken—viz., the girth of the patient at the level where the truss spring lies (viz., below the anterior iliac spines and above the great trochanters.) Trusses are kept, numbered identically with the number of inches in the girth of the persons they are most likely to fit. Moreover, it is not necessary to keep in stock separate trusses for ordinary inguinal and femoral herniæ. The same truss which fits an ordinary inguinal hernia can generally be, without difficulty, adapted to a femoral hernia of the same side. I have known persons to be very successful at truss-fitting who could seldom distinguish with accuracy between the two varieties. Let it be remembered how immediately adjacent is the femoral ring to the inguinal canal; they are separated only by Poupart's ligament.

The Exact Site of the Hernial Aperture should be determined.—Nevertheless, the surgeon will, of course, carefully make out the exact seat of the hernia, and will find the knowledge of great practical value in fitting the truss.

Examination in the Upright Position—Females.—As a rule the patient should first of all be examined in the upright position. In the case of females, the assistance of an experienced nurse, or, indeed, of any intelligent woman, will easily secure all the requirements of decency. The drawers must be loosened, and such parts as it is not necessary to expose guarded with a towel. The surgeon should bear in mind that he is dealing with a class of affections, highly dangerous to life, and insist quietly but resolutely upon a satisfactory examination. Sometimes the patient objects to a proper examination because she has neglected to put on clean linen or to take a bath. She then usually gives any reason except the true one. Sometimes she objects because the menses are on. Unless dangerous symptoms are present, the last objection may be regarded as a legitimate excuse for postponing an examination, but not for giving a truss without a proper examination at all.

Males.—In the case of men with inguinal hernia, the surgeon should inspect the whole genitalia. It is ludicrous to see some patients undo one button and exhibit a little space of skin the size of half-a-crown. Further examination of these modest people sometimes shows the "hernia" to be a bubo or epidydimitis accompanied by chancre or gonorrhœa.

Inspection.—The appearance presented by the hernia often indicates plainly the orifice from which it has escaped. For instance, a hernial swelling passing down into the scrotum from near the region of the pubic spine is inguinal and obviously not femoral. The same diagnosis may be made in the case of a hernia passing downwards into one of the labia majora. A bubonocele presenting at the site of the internal inguinal ring can also be diagnosed at the first glance. Similarly, also, a hernia which extends downwards or outwards into the thigh is quite certain not to be inguinal, and almost certain to be femoral.

Palpation.—When, however, a small hernia presents close to the pubic spine, that point of bone must be carefully made out by palpation, in order to find out on which side of it and of Poupart's ligament the hernial aperture is situated; in other words, in order to determine whether the hernia is inguinal or femoral. The inguinal canal can be directly examined with ease by invaginating the scrotum on the point of the forefinger. This procedure is not always one of such ease to the patient as it is to the surgeon. The part is sometimes exceedingly sensitive. Both the inspection and the palpation should first of all be made with the patient passive. Afterwards they can be repeated with the patient coughing. The reducibility and the amount of impulse are points which should be determined. Often, the patient having been without a truss, his rupture has been down even night and day for some time. A few minutes of the supine position on a couch, with the foot tipped up higher than the head, will usually enable the patient himself or the surgeon to reduce the hernia.

Measurement.—Trying on the Truss.—The position and reducibility of the hernia having been ascertained, the girth of the patient should be taken at a horizontal level just below the anterior superior iliac spines, and above the great trochanter (assuming the case to be inguinal or femoral), a right or left truss is then picked out of the proper size and applied while the patient lies down, his hernia being reduced. As the wearer lies thus on his back and wearing the truss, the latter generally appears loose and too large, but, when the erect position is assumed, the truss spring sinks into its place. The strap and perinæal band should be carefully adjusted with a view to retaining the truss pad over the hernial aperture. The perinæal band should be slipped into its proper place posteriorly.

Possible reasons why a given truss tried on does not fit.—Supposing that the truss so applied does not fit, the failure may be due to various causes. For instance, the truss pad may reach too far towards the linea alba and pubic symphysis. In that case the truss is too large, or the truss pad may scarcely reach far enough to cover the whole extent of the inguinal canal. In this case it is too small; or the size of the truss may be correct, but the pad fail to press exactly on the right spot or in the right direction. Now a truss spring has no business to be made like a sword blade, nor is it usually endowed with such perfect resilience. It is, therefore, possible for the surgeon with care and patience to weaken or strengthen the pressure of the truss, and even to so alter the shape near the pad, as to materially change the direction and position of its action. The metal back of the truss pad can also itself be bent if desired. Trusses can also be obtained with pads adjustable by screws.

Size of the Truss Pad.—The size of the truss pad need ordinarily bear no relation to that of the hernia, and it is really exceptional to meet a hernial aperture so large that an ordinary *well-fitting* truss pad will not command it. Many instrument makers are not of this opinion. The moment the slightest difficulty presents itself, or even before, if the patient shows a large scrotal hernia, an enormous machine with an outline like that of a cocked hat is clapped on. This is called a "scrotal" truss, and its size seems to be limited only by the necessity of leaving the mouth, anus, and meatus urinarius of the patient uncovered. When an ordinary truss pad does not safely retain a hernia coming through a large aperture, most satisfactory results sometimes follow from the use of a small piece of linen or lint folded several times and placed beneath the truss pad. Comfort, cleanliness, and effectiveness are secured together, as the folded linen pad can be changed and washed. With regard to reducible femoral herniæ, I can scarcely call to mind a single instance of one which required a very large truss pad.

Irreducible Femoral Herniæ.—It is the irreducible femoral herniæ which cause trouble. In the majority of such cases I believe than an operation for radical cure would be by far the best and safest mode of dealing with them (see *British Medical Journal*, December 5th, 1885); otherwise they must be fitted with a carefully *moulded* truss pad. But, as many of these cases are only partly irreducible, and as many yield gradually to the pressure of the moulded truss pad, there is a risk of its eventually giving room enough for a little knuckle of intestine to slip out and become strangulated.

Irreducible Inguinal Herniæ.—Irreducible inguinal herniæ requires the lace-up bag truss. With this, especially if combined with rest in bed and limited diet, the hernia will sometimes slip back, even after being down night and day for a very long period. The foot of the bed should be raised.

Curious Anomalies.—Very curious anomalies are presented by certain cases. I know of several men, past middle age, who are more comfortable with their herniæ down than up, and I know of one who wears a truss to prevent his rupture from going back. Its reduction causes great distress and pain. These cases could probably be brought to the normal condition by patient treatment in bed. Occasionally *both* femoral and inguinal herniæ occur on the same side. In such a case a double pad should be fitted to the same spring. There are usually two buttons on the back of each pad, the lower one for the perinæal strap, the upper for the girdle strap. In a few cases the truss is more comfortable or more effective with both straps attached to the same button. The material of the truss pad is not a matter of indifference to persons of means; but if the truss do but fit well, even the ordinary pad, stuffed with cork, etc., generally grows comfortable enough after a few days wear. There are great individual difference as regards the sensitiveness of these parts. An exceedingly comfortable and luxurious pad is the "glycerine pad." It is not part of the plan of this paper to discuss the merits of the various ingenious kinds of truss, and arrangements of the parts of the truss, which have been invented. Infants should have two trusses, so that one can be worn while the other is washed and dried. These trusses should be waterproof.

THE ETIOLOGY OF LEPROSY—A CRITICISM OF SOME CURRENT VIEWS.[1]

By P. S. Abraham, M.A., M.D., B.Sc., F.R.C.S.I.,

Lecturer on Physiology and Histology, Westminster Hospital Medical School, Clinical Assistant Hospital for Diseases of the Skin, Blackfriars; and late Curator of the Museum and Member of the Court of Examiners, Royal College of Surgeons, Ireland.

Putting to one side, for the present, the bacillus, which all pathologists agree is to be found in every leprous neuroplasm, the supposed etiological factors of leprosy which have been most considered of late years, are three, viz., (1) Heredity; (2) A diet of fish; (3) Contagion.

[1] Read in the Section on Dermatology and Syphilography at the Fortieth Annual Meeting of the American Medical Association, held at Newport, R.I., June, 1889.

The theory of heredity has had immense support, both lay and professional, and it is curious to observe how loth some medical authors are to set themselves free from its trammels, or to question its influence in propagating the disease, even though many of the facts which they themselves adduce seem obviously to lead to quite another conclusion. As Mr. Jonathan Hutchinson points out,[2] the fact of leprosy occasionally appearing in healthy immigrants, and just as severely as if such persons belonged to leper families, is enough to prove that hereditariness goes for little or nothing in its causation. It is indeed idle to deny the liability of leprosy to attack individuals who have not the slightest hereditary taint.

In a recent paper,[3] my friend, Dr. Blanc, who has in late years seen probably more cases of leprosy in the United States than any one observer, shows that in forty-two cases treated by him, twelve were natives of foreign countries (seven German, one Austrian, one English, one Irish, one French, one Italian), and of the remainder, eighteen were the the children of foreign born parents (chiefly German and Irish), "from which we conclude," he says, "that if the disease is hereditary, it must be derived from a variety of foreign sources; and if acquired then it seems to attack the children of immigrants as often as those of the older native families." What evidence can be stronger against heredity?

An important paper on the Heredity of Leprosy has lately been published by Dr. G. A. Hansen,[4] who made a journey to North America last year to see what had become of the Norwegians who had gone there as lepers or had developed leprosy after their arrival in the new world, and to study this question of heredity in particular. With the help of Dr. Hogh, of Minneapolis, and Dr. Grunwold, of Minnesota, he was able to find out that about 160 Norwegian lepers had been established in the states of Wisconsin, Minnesota, and Dakota. Many of them are married, and several of them have left a good many descendants. There are, in addition, many other Norwegian immigrants who are either descended from lepers, or have leprous relations in Norway. There is, therefore, in those districts, considerable material for the inheritance of leprosy. Of the 160 leper immigrants, only thirteen are left, which he himself saw, and besides these there are perhaps three or four others. All the rest are dead. Of all their descendants whom he has seen as far as the great grandchildren, not one has become a leper. This is, in short, the result of his investigations; and he says there can be only one explanation—viz., that leprosy is not inherited.

The Fish Theory.—In reference to this old theory, Mr. Hillis wrote in 1881 that it "may now be laid aside as obsolete;" and it is, I believe, almost universally discredited by the medical men in Norway, as well as in every other part of the world where leprosy is rife. Nevertheless, one who is justly regarded as one of our highest British authorities is still, it seems, an ardent believer in the view that the disease is contracted by the eating of fish, more especially fish which has been somewhat decomposed, or has been salted.[5]

Those who oppose this theory may well point out that while numbers of people in Scandanavia, in Africa, and in other countries, habitually regale themselves with imperfectly cooked or decomposed fish, and do *not* get leprosy, numbers of those who *do* acquire the disease are not aware of ever having eaten anything of the kind. (This negative argument is apparently at least as good as that largely relied on by the anti-contagionists, who infer that because many persons who come in contact, or even live with lepers, do not become lepers, therefore the disease cannot be contagious under any circumstances.)

If, indeed, it must be through *one* particular article of diet, in all parts of the world, that the germ of leprosy is introduced into the system, why may we not select something which everyone must swallow at some time or other, such as, for instance, bad water? Filters and other precautionary measures are, at any rate, not particularly fashionable in leper countries.

We really had no direct arguments against a possible dietetic origin for leprosy, *i.e.*, at least by means of contaminated food; and the view of Dr. Liveing promulgated in his Gulstonian Lectures so long as 1873[6]—viz., that the disease may be "propagated by the inhibition of the excretions of those affected, much in the same way as typhoid fever or cholera," may yet come to the front and secure further support.

The Contagion Theory.—Although clear and distinct instances of the direct communicability of leprosy from person to person are few and far between, and, from the nature of the disease, its latency and uncertain prodromata—difficult to prove, it appears to me that we cannot now deny its "contagiousness" in the sense that untainted individuals may occasionally become affected with the disease after being in close relation with lepers. As far as I can see there is no getting over Dr. Hawtrey Benson's case,[7] and as that careful physician remarks, "to ignore the evidence of contagion in this case, where the circumstances are so simple and so well authenticated, is indeed to strain scientific caution to its utmost limit, if not beyond it. . . . The proof of contagion afforded by this case possesses a force little short of that of a mathematical demonstration." I agree with him that "one such fragment of positive evidence carries more weight than a vast accumulation of negative evidence." In 1885, in his lecture on leprosy, Mr. Jonathan Hutchinson is reported to have said, "of course, if you are prejudiced in favour of its contagiousness, you can produce instances apparently in favour of it, especially if you reject a thousand negative facts in favour of one fact which seems to support it. I submit that no one who will read a record of the facts can ever believe that contagion can take place." There are other authorities, too, who, having made up their minds on the subject many years ago, are "of the same opinion still;" several, however, have seen reason to modify their views. Until a few years ago most of the Norwegian physicians disbelieved in the contagion of leprosy. Dr. Hansen, however, the discoverer of the bacillus, boldly asserted its infective character; and I found last year that Dr. Sand, of Trondhjem, and Dr. Kaurin, of Molde, have both come round to his way of thinking. The veteran, Dr. Danielson, however, is still of the old opinion—for, as he told me, "in all his long experience with the disease he had never met with one single instance of contagion." Dr. Nickoll also has no belief in the contagion of leprosy

nor indeed in its heredity, although, like Virchow and many others, he admits that there may be hereditary predisposition to contract the disease. He informed me that he had seen several cases, besides the one he has published, which point to direct contagion. Dr. Sand is of a similar opinion; and I learnt from him that he has known of two cases of servants—one at the Molde asylum and one at Bergen—having contracted the disease while in attendance on lepers. He knows, too, of many other instances which can be, at any rate, most satisfactorily explained by the theory of contagion.

Dr. Phillippo, of Jamaica, gave me last year his opinion as follows: "It is communicable by contagion. This has always been the opinion amongst most of the laity, and with some reservation, amongst many of the medical profession. Of late years I have known some most undoubted cases of contagion, and yet there have been many instances of relatives who have for years lived in daily intercourse of the freest kind, as parents and brothers and sisters, who have not suffered, and a small number of those who undoubtedly have. . . . . I know of cases where there was no hereditary disease, in which one member of a family has taken it from another. In one case, the husband, a European, took it from the wife. In him it ran a rapid course, and he died before her, though she had it for years before him. I know of cases in which this disease has been taken from outsiders, and have heard of others in which it has been taken from the wet nurse."

It is interesting to observe that Dr. Phillippo is one of those authorities mentioned by Dr. Gavin Milroy[8] as being opposed to the view that leprosy is contagious.

Dr. A. R. Saunders (M.D. Lond., F.R.C.S. Eng.), one of the leading practitioners (for fourteen years) of Kingston, Jamaica, has recently informed me that he has no doubt whatever as to the contagiousness of leprosy, and that he has under his care at the present time in Jamaica several cases which can only be explained by the theory of contagion. He ridicules the idea of a fish diet having anything to do with the disease.

Dr. Blanc, of New Orleans, states in the paper quoted, his belief, after a study of these forty-two and other cases, "that leprosy may be communicated from a leprous to a non-leprous person by means of a specific virus, which acts like a specific poison of syphilis, depending upon thin or denuded surfaces for its absorption, and which remains potent, very probably, for an indefinite period of time."

The doctors in the Sandwich Islands are all (and have been with one exception, Dr. Fitch, report, Honolulu, 1886), believers in the contagion of leprosy; as are many of those at the Cape, in India, in the West Indies, and elsewhere. Dr. G. H. Fox, of New York,[9] indeed says, "Now it is generally admitted by those who have most studied the facts of the case that leprosy is a contagious disease." He further remarks that "granting leprosy is contagious, we are forced to admit that it is so only to a very limited extent." Most people will concur in this.

Some of the ablest observers are still keeping their minds open on the question. Dr. Beaven Rake writes that he has met with no case of contagion in Trinidad, but that he can bring forward many negative instances. His inoculation experiments on animals, too, have been so far unsuccessful—as were those which were formerly practised on the human subject in Norway, in Mytelene, by Bargilli, and more recently in Sicily by Profeta. Even Arning's experiment on the convict at Honolulu, is, in Dr. Rake's opinion, not conclusive. This man, Keann, was inoculated September 30th, 1884, by Dr. Arning, "after having previously made a most searching inquiry as to any leprous taint in his family, and a close examination of his own body," which examination, says Dr. Arning, "satisfied me that, so far as I am able to judge, no trace of the disease could be found on him at that time.[10] Dr. Beaven Rake's valuable "Report on the Trinidad Leper Asylum for 1888," has just been kindly sent to me by the author. In it, in reference to this inoculation, he says, "When, however, we come to examine this question dispassionately, what do we find? A man living on an island infested with leprosy, was inoculated three years' ago with the disease, and has now developed it. But in that time he may have acquired leprosy in a dozen different ways—in air, food, water, etc., or it may have been in his family. True, the man was ascertained so far as possible to come of a clean family, and he has been isolated in gaol since the inoculation. Still, anyone who has attempted to take the statement of lepers will appreciate the value of family history; and in a country where leprosy is rampant, are we sure that it can be shut out by four walls? I repeat what I said in my last report, that an experiment of this kind, to be scientifically perfect, must be performed in a country free from leprosy, and in an individual who has never left that country, and whose immediate ancestors have always stayed at home."

Mr. C. Macnamara, then of Calcutta, discussing in 1866 the Indian Reports on Leprosy, in an able article in the *Indian Medical Gazette*, stated, in addition to other arguments in favour of the view of its contagiousness: "1. A large proportion of the civil surgeons in this presidency believe, from personal observation, that the disease is contagious. 2. The instances quoted from this report can only be explained by supposing the disease to be contagious."

Any opinion, however, which was favourable to contagion prior to the year 1867 went for nothing, for in their celebrated and authoritative report of that year, the Royal College of Physicians of London, made the sweeping statements, so often quoted, that: "The all but unanimous conviction of the most experienced observers in different parts of the world is quite opposed to the belief that leprosy is contagious or communicable by proximity or contact with the diseased. The evidence derived from the experience of the attendants in leper asylums is especially conclusive on this point. The few instances that have been reported in a contrary sense either rest on imperfect observation, or they are recorded with so little attention to the necessary details as not to affect the above conclusion." More than 250 replies to the interrogatories of the College Committee have been received from medical men and others located in the various leper centres, and a large majority of these were undoubtedly in the negative with regard to the communicability of leprosy from person to person. Some thirty-two or so, on the other hand, gave a more or less affirmative answer in reference to the question, and several qualified men actually cited cases in support of their views—*e.g.*, amongst others, Drs. Aquart, of Granada; Manget, of British Guiana; Regnaud, of Mauritius; Jackson, Harris, and Messrs. Macnamara, and Rose, of India. On looking over the report, it is difficult to see why the opinions of these gentlemen, many of whom had

[8] In his report on Leprosy in the West Indies, 1873, p. 30.

[9] In his "Remarks on the Treatment of Leprosy," New York, 1885.

[10] Appendix to Report on Leprosy, Honolulu, 1886, p. 43.

been for years in charge of lepers, should have been, apparently, considered so unreliable and worthless, in comparison with the others. The college, it seems, did not modify its views for years; but in 1887 we learn that "the committee are quite aware that there is much difference of opinion respecting the communicability of leprosy, and that many colonial practitioners and inhabitants do not concur in the views expressed by the college in their report in 1867."[11]

There is, indeed, as the Committee now admits (April 7th, 1889), "increasing evidence respecting the communicability of leprosy;" and it seems to me that we cannot ignore the cases reported, and the opinions formed upon them by such qualified observers as Vandyke Carter in India, Peterson and Münch in Russia, Besnier, Vidal, Leloir, and Cornil in France, and by many others of large experience and of high repute in all parts of the world.

In point of fact, however, any circumstances whatever—however strong they may be—which apparently lend support to the contagion theory, so long as they occur in a country in which leprosy is prevalent, are liable to be laid aside with some such "begging the question" remark as, that "after all it only amounts to this, that a person has become a leper in a place where the disease is endemic!"

In conclusion, I venture to express the opinion—after a somewhat extended study of the subject—that, with the facts at present at our disposal, it appears to be a pure assumption, unsupported by valid evidence, to say that leprosy can *only* gain a footing in the human body *per unam viam*.

Dr. Gavin Milroy, the secretary of the committee which scouted the idea of contagion, said, after his visit to the West Indies, that "leprosy appeared to him to be neither more nor less contagious than scrofula." We have no reason to assume that it may not be introducible in as many ways, although, perhaps, with much greater difficulty. The problem will, possibly, be fully solved when we know the whole life history of the microbe which is characteristic of the disease.

THE PROGRESS OF MEDICINE AND MEDICAL EDUCATION.[1]

By Claudius Galen Wheelhouse, F.R.C.S.,

President British Medical Association.

Life, as measured by the standard of the space of time allotted to each unit of the human family, is but a little span. Man has not reached his present condition of intellectual, of moral, or even of physical greatness in one generation; the white cliffs of Albion, in their formation, mark not only generations but æons in the progress of creation. Rome was not built in a day! So medicine, as she stands to-day, strong by the acquirements of her children of many generations, did not arise upon the world in the full glory of a heaven-born science; but, sifting grain by grain of her faith from the speculations laid at her feet by her followers through countless ages, has, little by little, built up the temple of her fame until it has assumed the proportions in which we now behold it, and of which we are the accredited custodians.

THE MEDICINE OF THE EARLY AGES.

Sometimes, in the current of events, her progress has been laboured and slow; with halting and uncertain steps, with Arabian mythologists, astrologers, and such like visionaries as her companions, she has picked her way through gloomy times of mystery, uncertainty, and doubt. At times the light of truth has shone upon her path more brightly, and has cheered her on her way; and with the Harveys, the Sydenhams, the Jenners, and the Hunters, the Dupuytrens, Laennecs, and Pasteurs of the world for her companions, she has walked with firmer steps, until at last she has become an acknowledged power, and stands forth as the companion of even the exact sciences. Each generation of her votaries, as it passes across the stage of the world's history, is henceforward bound to leave a mark behind it as its contribution to the sum of existence, and that mark must, in the aggregate, be the result of individual efforts. I can look upon the broad roll of this great association, and can see there names that will never die—the names of men whose achievements will never perish, who, when they sink as their predecessors have done, to their rest, will leave, as Harvey and Jenner left in former times, a priceless inheritance to mankind at large, whose labours will not have been in vain, and of whom the world will acknowledge that the talent intrusted to them has been productive of abundant fruit, that of a truth they have left the world better and richer than they found it. I can see hundreds of others who are aiming at this high standard, who by their individual labours are raising the great tower of knowledge, and whose lives, though not illuminated by the torch of genius, will yet leave behind them the undying results of patient labour in well-doing; and I see, in all, the roll of a great brotherhood, strong in their efforts to advance the common weal, and doubly strong in the strength of union.

THE LEEDS MEETING.

You, by your unfailing kindness, have on many occasions so brightened my life that I should be ungrateful indeed if, on an occasion such as this, I failed to offer you my warmest and most grateful acknowledgements and thanks. On one occasion you placed me at the Council table of the Royal College of Surgeons; on another you sent me as your "direct representative" to the General Medical Council; for three years you placed the highest interests of this great association in my hands as your President of Council; and now, on the occasion of your third visit to our town, you have done me the supreme honour of asking me to fill your presidential chair, and to undertake the conduct of what I sincerely trust will be a great and a successful gathering. On behalf of the profession of Leeds and the district I most heartily bid you welcome. I join my fellow-townsmen and our neighbours in adjoining towns who desire to share with us the pleasure of receiving you, in the hope that the week you are about to spend with us may be a happy one, may be productive of scientific benefit, and may prove of social value; that the arrangements we have made for your comfort may work well, and may conduce to your enjoyment. To us your acceptance of our invitation and your presence among us are matters for great rejoicing, and we sincerely hope that, when our meeting is over, you will still hold Leeds in the esteem we prize so highly. The bill of fare we have provided for your enjoyment will meet, we hope, with your appreciation and approval; and if we have ventured upon the introduction of some few novelties and variations in the usual plan of the annual programme, we have done it

[11] Vide "Leprosy Committee Report," *R. C. P.*, July 15th, 1887.

[1] Abstract of the Presidential Address, Leeds meeting of the British Medical Association, August 13th, 1889.

in the sincerest hope that we may thereby advance and increase the interest of your sojourn among us. My duty is an easy and pleasant one.

I am precluded from speaking to you on any of the directly special subjects with which we are called upon, whether as physicians or as surgeons, to deal. Medicine will be discussed, and all that can be said of it will be brought before you by one of the leading physicians of the day; and in Dr. J. Hughlings Jackson you will find an exponent to whom you will join me in listening with hearty interest and attention. Surgery, and the progress it has made and is making, will be dealt with by my friend and colleague, Mr. T. Pridgin Teale; and for, I believe, the first time in the history of the association, an address in psychological science will be offered you, and this we have placed in the very able hands of our former tried and ever-welcome friend, Sir James Crichton Browne. Our sections will be presided over by men who, each in his own department, will tell us all that it is necessary for us to know to keep us abreast with its latest and highest developments, and, as individuals, you will have an opportunity, in the discussions which have been arranged for you, to bring forward any special matters with which you wish to deal, on which you may personally wish to be heard, or to impart to us any information which you have acquired or have worked out. To do this has ever been, and is still, the great object of our association; and who can calculate the advantage that has accrued to us, as a profession, from the accumulated labour of the fifty-seven years during which it has existed?

THE COMPARATIVE ISOLATION OF PRACTITIONERS IN FORMER TIMES.

We, in comparison with preceding generations, have been possessed of advantages of incomparable magnitude, not only in our own, but in every other science also. Knowledge and the facilities for the spread of knowledge have so increased that comparison is almost impossible. Think for a moment of the changes one generation only has seen! What great discovery can now be made that does not instantly become the property of even the remotest nations of the world, and is not, by an omnipresent press, brought to the personal knowledge of every votary of science? What did the surgeon of fifty years ago know of the powers of "germs," of "bacteria," of "bacilli," and of their capability to destroy his most elaborate and perfect work?

And where is the student of surgery of the present day to whom they are unknown, or who is unprepared to do battle with them, one and all, and to baffle or to modify their evil influences? What the medicine and surgery of the eighteenth and preceding centuries were, we are only able to conjecture. Its medicine we believe to have been little more than an empiricism founded on close observation, and led by a few master minds; and its surgery we know was crude, and, as compared with that of to-day, was even barbarous and cruel, and few of us I imagine would care to witness a major operation, as then performed, by even the most renowned and skilful surgeon. But the light, even then, was breaking, and not many years of the present century were to run ere truer principles of both medicine and surgery were to be made known to the world, and each was, as a science, to be established on a surer foundation than any on which it had hitherto rested.

THE GENERAL PRACTITIONER OF THE EARLY PART OF THE PRESENT CENTURY.

Let me endeavour to draw a sketch of the average practitioner of the commencement of the present century, and there may be some, at any rate, in this room, who can follow me and judge whether I paint him correctly, or whether, trusting too much to tradition and report, I do him injustice.

He was usually a hard-working industrious man, who thought little of bodily exertion, and who spent the greater part of his time in his saddle, which was his only way of getting about the country; a hard-thinking man, but one whose mental training had not been great, nor his education elaborate; whose opportunities for the acquisition of professional knowledge had been few and short; of whom it might be said that that which he knew was, in the main, either the fruit of his own observation, or of his own observation added to the traditions of the place or practice in which he had been brought up.

Knowledge and practice alike were purely empirical with him, and though he could treat disease with skill, and could, in most cases, give a good account of his warfare, it was purely by empirical means that he did it. His great panacea for all ailments was blood-letting, and his pocket was never unarmed with the all-potent lancet.

As a Physician.—No matter what the case might be, so long as it was "acute," venesection must precede everything else; then followed a superabundance of mixtures, powders, draughts, pills, lotions, and so forth, with which he hoped to effect a double purpose, first, to cure his patient, and secondly to remunerate himself for his attendance; for, so trifling were the charges he was able to make for his personal labour, and at so low a rate was that estimated by his patients, in comparison with the amount of medicine he gave them, that, except for the additional charges made for it, his remuneration would have been infinitesimal. He had a good sound knowledge of drugs in general, and of what they could do; he was sadly too ready to rely on them, and his patients were compelled not only to swallow most nauseous compounds, but to swallow them also in inordinate quantities. Of the morbid anatomy of disease he knew something, but not much; of pathology, in its true sense, he knew nothing, for physiology, whether healthy or morbid, was not one of the sciences of his day. When he "walked the hospitals" for the few months required of him, he saw a few *post-mortem* examinations, and had the opportunity to mark the ravages and the appearances left by various so-called diseases, and these he was apt to regard as the diseases themselves. His treatment was chiefly based on nomenclature; he could tell you what was good for "fever," what for "tic," for "rheumatism," for "indigestion," for "scurvy," and for innumerable other complaints; and he who was believed to possess the greatest number of formulæ for the greatest number of complaints was regarded as the cleverest and most desirable doctor.

As a Surgeon.—As a surgeon he was, as a rule, further behind the practitioner of to-day than he was as a physician. His education, such as it was, had taught him to rely, in this branch, more on the skill of others than on his own. There were certain men, well-known in their several districts as the men to whom to appeal in cases of surgical emergency, and they were the men who made world-wide reputations.

Leeds possessed one such surgeon, whose name was known, not only in every hamlet in Yorkshire, but, even in

that day, all England over, William Hey; and we are proud, even to-day, of that reputation, and that we possess a statue of him which, while it points the moral of the fame to be attained by industry, ability, and rectitude, is an ornament also of the noble hospital which enriches our town, and of which he was one of the founders.

What William Hey was to Leeds, Sir Astley Cooper and many others were to their London *confrères*; and so, scattered all the country over, were there others to whom, in times of surgical emergency, or for great surgical skill, the country practitioner was wont to look, and as a natural consequence surgery remained an art but little cultivated by the general practitioner. Nor for this was the practitioner alone to blame.

SURGICAL OPERATIONS IN FORMER TIMES.

A surgical operation in those days was an ordeal of fearfully different magnitude to anything known to us to-day, and, naturally enough, the patient had a large say in the matter. Confidence in operations themselves and confidence in the skill of the operator were not then what they are now, and it must be remembered that when, as the only means of escape with life, an operation had to be performed, it had also to be endured in all its unalleviated agony. Courage and endurance, unfortunately, are not given alike to all, and many a life which would be saved to-day was at that time voluntarily laid down, not simply for want of faith in the capability of the surgeon, but from sheer inability to face the terrible ordeal of bodily suffering involved.

APPRENTICESHIP.

The practitioner was not called upon, on entering the profession, to prove himself in any way specially adapted for it. It mattered not what his education or want of it had been, no test was required of him. In the majority of cases he was, as it were, in a manner born to the position, as well as to the particular practice in which he was destined to take part; and, under any circumstances, he was called upon to serve an apprenticeship so prolonged as to be almost the same thing.

For the first five years of his professional life, he was compelled to devote himself to what seemed, perhaps, at the time, the simplest and most abject drudgery; but at the same time he picked up, all unconsciously it may have been, but none the less certainly, knowledge destined to be of infinite value to him in after life—the knowedge of common diseases; and when, after his few short months of hospital experience he entered on practice, he did so with a fair all-round idea of its ordinary requirements, and he trusted to extraneous help in emergencies and unusual difficulties.

So, taking him for all in all, our forefather in the early part of the century was pretty much what the times were calculated to make him—a shrewd, keenly observant, self-contained, and self-reliant practitioner, whose education, whether general or professional, had been but scanty, whose means of intercommunication with his fellows were few, and whose professional position and value were very much what he himself chose to make them. That he did excellent work in the world no one will be willing to deny; and we, who are endeavouring to carry on and improve upon his efforts, should be the last to deny him the meed of praise he so abundantly earned.

THE MEDICAL SCIENCE OF THE PRESENT DAY.

That the medical science of our time is in advance of the time of which I have been speaking is beyond question, and that the effects produced by increased knowledge and research have given advantages to the world of indescribable value, no one will deny. In a large measure it is due to our possession of vastly improved instruments of precision. To our ancestors the revelations the microscope has made to us were but a dream. They could theorise and argue and believe, but the things upon which they could only theorise and argue and believe are living verities to us. To them the existence of a *materies morbi* was only an argument, whereas now, we know not only that the causes of many diseases are indeed material, and even tangible, but that we are able to demonstrate and see them, to recognise their individuality, their specific forms, and the phenomena of their growth, propagation, and development. I call to mind a story of two great Scotch professors—the one a theorist, the other a materialist. The materialist would argue that certain forms of disease must be due to the presence of germs, and were the direct results of their development, propagation, and multiplication; and the theorist would cry, "Hero is your microscope, show me but one of the germs and I will believe; but, until you do, I cannot," and being unable to do this, his friend could only fold his hands and wait patiently, hugging his belief meanwhile, but with the conviction of certainty none the less. Gentlemen, picture these two professors now[2] if they could meet, and know only as much as we know of bacteriology, and of the field of germ pathology. And meanwhile, yet another Scotch pathologist, as fully convinced as though he could see or had seen the whole range of modern pathological development, so ponders the theory, and acts upon what he believes its possibilities to be, that, at last, he lays at the feet of his profession the whole science of antiseptic surgery. So, in like manner, and little by little, the microscope has revealed to us many of these hidden mysteries which constitute the whole science of physiology, has shown to us the beauties of capillary and lymphatic circulation, has enabled us to understand and comprehend the processes of absorption, of disintegration, and of recuperation, and has placed at our disposal the key to mysteries of which our predecessors could have but faint imaginings, but which we know, and know with a certainty which constitutes our knowledge. Thus medicine and surgery have alike been founded on a rock of knowledge from which they can never henceforward be dislodged. And so, by other instruments of precision, barrier after barrier has been cleared away, and we now see clearly where heretofore we had only seen as "in a glass darkly" and unassailable stores of knowledge have thus been placed at our disposal. What shall I say, for instance, of our advance along the pathway opened up to us by electrical science? Is not this alone one which, uncomprehended in former times, has enable us to build up knowledge of phenomena, without which the infinite intricacies of the action of the nervous system must have remained shrouded in profound darkness, and out of the chaos of former mysteries to see, clearly defined, order and law where ignorance, hypothesis, and mystification formerly had reigned supreme? And while physiology has thus grown into a true science, pathology has also advanced with equally rapid and giant strides. And so, with ceaseless patience we endeavour to track down mischief to its origin and birth. Year after year our patience is rewarded by fresh discoveries, and thus, each year. the tree of knowledge puts forth fresh

[2] Professor J. Y. Simpson and Hughes Bennet at the last meeting in Leeds.

shoots and brings us a more and more abundant yield of goodly fruit. Advances, however, of such kinds as these, and in such directions, do not in my opinion, constitute the chief or highest glory of modern medicine.

PUBLIC MEDICINE AND THE AIMS OF THE PROFESSION.

A common reproach is often brought against both medicine and its practitioners that it is a sceptical profession; that its practitioners are essentially materialists in their view; that medicine, as a science, leads to free thinking, and seeks, in a rational explanation of every fact with which it is brought into contact, to undermine our belief in things spiritual, and to lessen our faith in all that we cannot see, and handle, and account for; that constant contact with pain and suffering tends to numb our sympathy and to diminish our pity for the sufferings of mankind. On this point I would venture fearlessly to challenge any other calling or profession to produce a parallel to the modern development of "public medicine," a science which seeks ever, even at the risk of its own extinction, to exterminate the causes of disease and death, and to eradicate from the world the very springs and sources from which they arise. "It is a common-wealth sustained and governed by the desire existing in the minds of each of its members to do as much good as possible to every other member. It looks upon prevention as better than cure, and asserts, as is now clear to all, "that a large part of human suffering is preventable by improved social arrangements," and sets itself the task of sweeping away all such preventable causes. Its compassion is all the deeper, its relief more prompt and zealous, because it does not generally, as former generations did, recognise such calamities to be part of man's inevitable destiny; and it hurries with the more painful eagerness to remedy evils which it feels ought never to have befallen. Our Great Example commanded his first followers to heal the sick and give alms, but He commands us and all His followers in this age to investigate the causes of all evils, to master the science of health, to consider the question of education with the view to health, and while all these investigations are made with free expenditure of energy and time and means, to work out the re-arrangement of human life in accordance with the results they give; and if, instead of undoing a little harm, and comforting a few unfortunates, we have the means of averting countless misfortunes, and raising, by the right employment of our knowledge and power of contrivance, the general standard of happiness, we lessen the necessary evils of life, lengthen the term of human existence, wipe out the causes of innumerable griefs and sufferings, make life more endurable and happy, can it be said that we are failing to obey the commands or to undermine the teaching of our great Master?[3]

Can it be denied that these are among the chief aims and objects of our profession in this our day? Is not every community provided with its officer of health? Is not disease of every kind assiduously and ceaselessly tracked to its hidden birthplace? Can an epidemic now run riot as it did in former times? or devastate a whole country, as it formerly was wont to do? So, then, in our daily life as the servants of our fellow-creatures, in our eager race after improvements, in our efforts to spread abroad over the earth the results of the knowledge we attain, I hold that the practitioners of medicine of the now closing century have not been left behind in the race of life; that we have won our laurels, and have been faithful to our trust. And as we exult in the progress we have made, and are humbly thankful, so let us hope will those who follow after us, outshine our accomplishments, and leave us in turn very far behind them in knowledge and in power for good.

[3] See *Ecce Homo*, chap. 17, "The Law of Philanthropy."

MEDICAL EDUCATION IN THE PAST.

But, on an occasion such as this, and with such an assembly for my audience, I cannot refrain from discussing, or attempting to discuss, a question which, while of deep interest to us, is of vital importance to those who will succeed us, namely, the medical education of the day. Are we doing the best that can be done for the practitioners of the future in our method of training them? The answer to this question involves an inquiry which must at any time be a formidable one, and one which to many people seems almost, if not quite, unattainable.

"Quot homies tot sententiæ;" in every large gathering of medical men opinions will be found at variance on the subject, and yet, untill something like general accord can be attained, it is hardly to be expected that the difficulty will be overcome, or a safe solution be arrived at. During the last fifty years the knowledge to be acquired by medical men has increased a hundredfold, and the educational status of our students has, of necessity, been correspondingly advanced. In the early days of which I have been speaking no educational test was applied to those who desire to enter the profession; candidates might be almost devoid of education, and many were of so rough and uncultivated a class as to bring on the medical student a very unenviable notoriety. Happily this difficulty has been amended, and the students of to-day are represented by a body of youths of whom the country may be reasonably proud. The medical student of to-day is usually an industrious and steady man who not only seeks sound information from recognised sources, but who is given to investigation on his own account. His time is, on the whole, devoted to its proper objects; he takes work seriously, and small blame to him if, now and then, he takes his pleasure hilariously, so long as he ever remembers that he is a gentleman, and is qualifying himself to carry the colours of a gentlemanly calling.

"All work and no play makes Jack a dull boy" in medicine as in everything else, and medicine does not want dull boys among her followers, and the student of the present day usually turns out a thoughtful, studious, and observant man, well trained for the work of his profession. But he needs certain practical and mental qualifications, qualifications possessed by his predecessor, but still to be picked up, so far as he is concerned, during the early years of active practice, and which are not to be attained in any other school than that of serious and anxious responsibility.

Fifty years ago our plan of educating such a man was this. For five years after leaving school he was compelled, as an apprentice, to begin at the beginning, to learn, while his mind was teachable, the A B C of his profession, to watch and observe the practice of his master, and to pick up in a general way the reason why of all that he saw done. When old enough, and qualified to do so, he was often permitted and encouraged to try his prentice hand himself, and to help in many ways under the guidance of his superior. Then he was sent for three years to a hospital or medical school, and there by the study of elementary chemistry, of materia medica, of medicine, of practical anatomy and surgery, by lectures and clinical instruction

at the hands of able teachers, both medical and surgical, he was shown the best of all work done in the best possible way, and he thus obtained a ground work of knowledge and information sufficient to make him a safe practitioner of the town, and capable of any amount of expansion in the future.

MEDICAL EDUCATION IN THE PRESENT.

Year by year and little by little we have been accumulating a burden which, if not absolutely more than the shoulders of a youth can bear, is yet heavier than he can possibly carry with credit; and instead of increasing his opportunities to acquire the strength necessary to bear it, we have curtailed his time, have deprived him of material advantages, and, in accordance with the hurry of the age, have demanded results well-nigh impossible of attainment. The five years of apprenticeship have been swept away, and with them the opportunity to master the groundwork of medical education and to acquire a sound knowledge of the more common forms of ordinary illness has gone also; and in four years, instead of eight, we permit the whole work to be completed. We have determined to ignore the utility of that homely but infinitely useful form of preparation for the higher parts of medical education which apprenticeship or pupilage was pre-eminently calculated to afford; we have determined that from the day on which a boy has been able to pass a very ordinary and limited educational examination he shall be permitted to take his place in a medical school, and we have arranged a curriculum which, if by dint of slavish toil he can master, shall enable him, at the early age of twenty-one, to enter upon the full responsibilities and duties of practice.

THE GREAT BURDEN OF MODERN EXAMINATIONS.

We demand of him that he shall pass at least four examinations. One in general education; then a preliminary one in his professional subjects, at the end of his first year of professional study; a "primary" and a "pass" examination; and to make this the more easy to him we permit him, if he wishes to do so, to split up these four examinations into eight or even ten, and by clearing them off in fragments, we give him the opportunity to dismiss study after study from his mind with a rapidity which leaves scarcely a trace of them behind, and enables him to forget them, one after another, with a facilty which, if the mere capability io pass examinations were the only end and object aimed at, would be commendable enough; until at last there only remains the one final test, at which, by a supreme effort, he may show that he has attained a sufficient amount of theoretical knowledge to satisfy his examiners, and that he has acquired a fair comprehension of the principles which underlie his future work. That even this is impossible, or nearly so, is abundantly proved by the fact that in a large majority of cases men voluntarily, and in many more under the compulsion of failure in the earlier examinations, devote five years instead of four to their education, and find that even then the task has been almost more than their powers could endure. To make up for deficiencies which even to themselves are then only too apparent and too keenly felt, hospital appointments, whether paid or unpaid, are eagerly sought for and accepted; or, failing to obtain these, men seek for themselves assistantships in which they may obtain that practical knowledge which only work under the guidance of experience can give them, and for lack of which they feel and know that they are unfit to cope alone with the responsibilities of practice. In one thing the new system is unquestionably superior to the old.

It takes its stand upon a higher grade of education, both general and professional; and of two men educated, one, on the old, and the other on the new plan, when they have been equally for a few years in practice, the latter will probably be the better practitioner of the two. He will then have picked up what the other had already acquired to begin with, and will henceforward easily distance his competitor in the race. But I do not envy him the experience of those first five years.

UNQUALIFIED ASSISTANTS.

The General Medical Council, with a laudable desire to diminish the evils of unqualified practice, has determined as far as it is possible to put down the employment of unqualified assistants, and it thereby unquestionably aids the young and recently-qualified practitioner in his attempt to complete an education which ought to be complete already. But there are two sides to this question, and it has to be regarded from the point of view of the employer also. He, when engaging an assistant, is presumably seeking the service of one who will be a help to him, and not of one who, though nominally an assistant, is in reality a pupil, and who, though he be very learned in all the highest wisdom of the schools, is startled by the appearance of so extraordinary a rash as that presented by "sudamina," for instance, and who, though he can tell an examiner glibly enough the number of days necessary for the incubation of varicella, rubeola, variola, or scarlatina, and all the theoretical details concerning the history, course, complications, development, and sequelæ of these various diseases, is "not quite sure," when he sees them, which is which, and would, therefore, like his principal to see them before he ventures upon their treatment. This is not an overdrawn or fancy picture; it is a sketch from life; and although, happily, it may not be an invariable one, nevertheless it is one we elders in the profession not infrequently see, and which makes us just a little sceptical as to the superiority of modern over former methods of education. It happened to one of my colleagues not very long ago, when called into the country to perform the operation of lumbar colotomy, to be provided with the assistance of a gentleman of this order, who, when requested to administer an anæsthetic, was compelled to admit that he had never done such a thing in his life, that he knew nothing about it, that he has never passed a catheter, or drawn a tooth, and yet he had passed the examinations.

I know there are many men who feel strongly that this is the time when pupilage would be most advantageous, and in the discussions of the Education Committee of the General Medical Council, as well as elsewhere, I have heard it strenuously argued; but the view is one which does not commend itself to my judgment, and which a long course of observation has not tended to confirm.

TIME FOR PUPILAGE.

I hold that the time to acquire simple information is when the mind is eager, inquiring, impressionable, and plastic; when mistakes and failures are of comparatively little momoment; when a little wholesome ridicule may be borne with equanimity, and when lessons which are the outcome of inexperience leave well-defined impressions on the mind which serve as warnings and landmarks at a future and more important age without any bitterness or sting in their remem-

brance. In later life, especially at that particular time of life when a young man is, perhaps pardonably and not unreasonably, a little elated and puffed up by having passed all his examinations, such failures, and the rebuffs they bring in their train, are neither so well borne nor so productive of advantage, and they constitute an evil which may be avoided.

In our large county hospitals, workhouse infirmaries, and public dispensaries, which, up to the present time, have been but very slightly utilised, we have a splendid field in which a vast fund of information of this kind, which now runs to waste, might be gleaned; and of these I would make much greater use than has hitherto been the practice. In pupilage, in one or other of these, in my humble judgment a year, or even two, at the commencement of professional study, would prove the very best beginning; and in following the practice to be there seen under the direct guidance and supervision of those who administer them, a youth would see work which in after-life would be of incalculable value to him, and would obtain opportunities for a groundwork which, under the present method of education, are wholly thrown away.[4]

MODERN EXAMINATIONS.

I would earnestly plead also for a radical change in our modern system of examinations. That they are capable, as at present conducted, of great improvement will, I think, be very generally admitted.

Their Inadequacy.—That they fail in their essential object—the discovery of those who are fit and of those who are unfit to enter upon the responsibilities of practice—is undeniable; and, while I admit that the effort to do this is always conscientiously and most praiseworthily pursued, I am satisfied that they often—far too often—wholly fail in the attainment of their intention. During a long career as a teacher, systematic and practical alike, I have watched with the keenest interest the success or failure of those whom I have trained, and many and many a time my heart has failed me when I have seen those whom I have known to be conscientious, painstaking, and thoroughly well-informed men sent down, while others, of whose records I should have been sorry to speak, have passed with flying colours.

Their Great and Unnecessary Multiplication.—I have already spoken of the number of examinations—"an appalling number," as they have been publicly called by my friend, Mr. Teale—demanded of the modern medical student before he can claim to be placed upon the *Medical Register*, and I pray you to consider with me for a few moments what they involve.

Their Costliness.—For each one his presence in London or at one of the capitals of universities of the kingdom is necessary; and divided as they are into "written" and "oral" and "clinical," think of the terrible waste of time and of money that is expended upon each. Take the simple instance of one, the "primary" at the united colleges. The candidate must go to London, and submit himself first to the ordeal of a written examination. This he has to do against time and under most unfavourable conditions. A certain number of questions are given to him on a printed form, and he is told that within a certain definite time he must have answered so many—not necessarily all, but a given proportion—and that unless he can succeed in doing that he need trouble himself no further.

The Hurry and Worry under which they are Conducted.—Thus he is compelled to think against time and to write against time. He has no opportunity deliberately to marshal either his knowledge or his facts, or to consider how he can show them to the greatest advantage. He scrambles all he knows of any given subject, or can hastily call to mind, into his paper, and, whether it be ill-written or well, he must abide the consequence! And to how many does it not happen that the moment the ordeal is over, the paper irrevocably handed in, the overstrain relaxed, that there rush in upon the memory many points overlooked or forgotten that would be joyfully added if it were possible. But that cannot be; he must be content to be adjudged ignorant of those things which he has not actually written, and must abide the decision of the examiner with such patience as he is able to command.

The Ordeal to the Examiner.—Then comes the equally terrible ordeal of the examiner, whose duty it is within a certain given numbers of hours or days, as the case may be, not only to read oven the papers handed in to him, but to adjudicate upon the value of each answer. In public discussion of the subject of "examinations" generally, recently held in Leeds, Mr. Teale told his audience this startling fact—namely, that a young examiner had confided to a near relative of his the information that he had to look through fifteen hundred sets of answers in a fortnight, and that they would have to be done at the rate of five minutes for each paper! Meanwhile, the candidate, though his effort may have fallen far short of the standard required, is not—probably cannot—be informed of his failure; he is still required to present himself for the *vivâ voce* portion of the examination, and for this purpose either a journey home and a second to the seat of examination is necessary, or he must stay where he is until his fate has been decided.

AN ALTERNATE SCHEME.

Years ago I suggested to the Council of the College of Surgeons that much, at any rate, of this difficulty might be overcome by conducting the written portion of the several examinations at the seats of teaching, as is done with the university local examinations. The question papers could be forwarded under the seal of the examining body to the official in charge of the local examination room. The seal could there be broken in the presence of the candidates, and the examination could be so safeguarded as to render collusion as impossible as in London or elsewhere. To the candidate such a time as he felt that he honestly needed could be given, and the element of hurry, at any rate, so far as he is concerned, could be eliminated. The answers, when handed in, could be sent, again under seal, to the examiners with absolute safety, and all this at an almost nominal cost. The examiners, in their turn, could take reasonable time in which to form an accurate judgment of each set of papers; and last, and most important of all, those of the candidates who so entirely failed as to make all hope of their passing an impossibility, might be informed that that was so, and that their presence for further examination was not, on that occasion, necessary. By this plan time, labour, money, and heartburning would be saved, and a feeling of justice and fairness, unquestionably lacking

[4] In the Leeds Public Dispensary alone last year 36,046 patients were examined and prescibed for, and 19,118 visits were paid by the members of the staff to patients in their own homes.

under the present system, would be engendered; and, as with this, so the same proceeding could be carried out with all the other examinations. And yet, as examinations are at present conducted, one great thing would be lacking; they would lack any guarantee of the possession by the candidate of that practical knowledge which we some of us feel to be the great want in modern medical education. This I, if I could have my way, would thus supply. I would make the first step in the purely medical part of the curriculum a year, at any rate, of practical pupilage. So soon as the "preliminary" or education examination had been passed, I would insist that the next step should be residence for one year either with a general practitioner, or as a pupil at a county hospital, or in connection with a recognised public dispensary, where, under the observation and guidance of the acting officers, the pupil might see, day by day, the general run of every-day practice, and would become familiarised with the common ailments of daily life as seen in the homes of the people; where he would become acquainted, and that practically, with all that he would be called upon to undertake, or would meet with in the early years of actual practice; where all the simple and minor operations of surgery would be seen and learned in the best, because most practical, manner. Then I would send him for four, at least, full years to a medical school and hospital to learn the why and the wherefore of all that he had already picked up, and to learn all that is so admirably taught in those most admirable schools. I would not permit him to fritter away his examinations in scraps, but, at the end of the second year, I would institute one, full one, to embrace all the preliminary studies which had occupied him so far, and, by delaying all else to the end of the curriculum, I would compel him to keep all his knowledge well in hand, and would then institute such a full and complete examination, both theoretical and practical, as should be an indisputable guarantee of his possession of the requisite knowledge to make him a safe and reliable practitioner. This is done now in Germany, and the example is one we should do well to follow.

At that examination I would also have placed in the hands of the examiners a minute and careful analysis, drawn up by the teachers, of the character of every candidate; this should be accompanied by a certificate of his pupilage, and should declare, on the responsibility of those under whom it was served, that he had been made conversant with daily out-door practice, and had himself performed the common operations of minor surgery. At any rate, whatsoever may be the course that future examinations may take, I sincerely hope their number will be diminished, that they will become more and more practical in their character, and that they will be made to include a knowledge of every-day occurrences rather than of such as are likely to come but rarely under observation. Further, I confess to being sufficiently old-fashioned to desire to return, in a greatly modified form, to some system of pupilage, by which a true foundation may be laid, by an early acquirement of the knowledge of common things, for that vast superstructure which the medical practitioner of the future will be called upon to raise and carry.

THE FUTURE AND ITS WORK.

I have now endeavoured to recall to your memory the character, the achievements, and the capability of the practitioner of former times. I have shown you how infinitely greater is the knowledge and the utility of the practitioner of the present day. We know how he has brough every region of the body, even those which were formerly deemed wholly beyond the sphere of his influence, such as the contents of the cranium, the vital organs of the chest, of the abdomen, and of the pelvis, under the dominion of our science; that, by the institution of preventive medicine, he has swept away many of the approbria, and of the direst scourges of former times; and it only remains to indicate in very few words the still vast field of further utility that lies open for cultivation by the practitioners of the future.

There is one plague spot, I fear, which even he will fail to conquer; which will remain to fester, to kill its thousands, to maim, disfigure, and to sap the health of millions, of deserving and of undeserving alike, and, as the great curse of humanity, to baffle all our effort to arrest the progress of disease, and to render them futile and abortive. You know the curse to which I allude; the curse that steadily and vindictively pursues the track of licentiousness, of ungoverned passion, of hateful sensuality; and you will admit with me that so long as human nature remains what it is, and is left in unbridled possession of the means of gratification, no ray of either light or hope will fall on that dark track.

Some day men may have become sufficiently enlightened to submit to necessary legislation and restrictions on this and cognate subjects; but, until they do, the foul stream will continue to meander hither and thither, and whithersoever it will through the world of life; will poison its springs, will wither even its fairest blooms, and destroy its richest fruits without selection and without mercy. By the cultivation of bacteriology and cognate sciences, by a deeper and more profound acquaintance with natural phenomena and laws, I can foreshadow in my mind the time when the whole range of zymotic and exanthematous diseases will have been subdued and conquered; when the seeds of each will have been isolated, and so studied that their individuality will be recognisable; the soils in which they will grow and those in which they will lie sterile will be known and appreciated, and be brought under cultivation by the hands of the medical men of the day; when the methods of dealing with them will be such that they may be reduced to harmless quantities; and when, by the spread of sanitary science, the whole human race may be protected from their evil influences. It will not be in our day that these mighty triumphs will be won, but our successors will undoubtedly achieve them; and the time will certainly come when the kingdom of disease will be so closely narrowed down that only the necessary accompaniments of the changes and vicissitudes of natural laws, the evils attendant upon the wilful disobedience of those laws, the innumerable accidents to which life and limb must be for ever liable, and the inherent defects and deficiencies in the harmonious working of the parts of a machine so exquisitely and delicately constructed as is the frail body which, for a time, we inhabit will be the only kingdom in which the professors of medicine and surgery will be called upon to exercise their sway. Then will the victory of our science be complete, and the day will have come when the world will be called upon to acknowledge that the labours of the physician and the surgeon, patient, enduring, untiring, as they have been through all time, have not been in vain, and have reached their final consummation.

HEALTH RESORTS OF THE WORLD.

XXXV.—SWANAGE.

By W. Armstrong Willis, Monmouth.

Swanage is not so well-known out of Dorsetshire as it deserves to be, though it has long been held in esteem by the inhabitants of Dorset and their neighbours in Hampshire. The town itself is situated between Swanage Bay and Durlston Bay, the separation between the two bays being made by Peveril Point, and they are cut out of the most southerly end of that great curve of the sea which forms Poole Bay (in the centre of which is Bournemouth), and Christchurch Bay. Swanage is the chief town in the Isle of Purbeck, as this large peninsular district is rather incorrectly named. Besides the sea on the south, the large system of land-locked lagoons, known as Poole Harbour, form a barrier on the north of the Purbeck District, and cut it off from direct land communication with Poole, Parkstone, Bournemouth, and Christchurch; to this isolation of position much of the charm of Swanage and the neighbourhood may be attributed. Of quite recent years Swanage has been connected by rail with Wareham and the South-Western Railway, and is now a most accessible place from London and elsewhere. By situation it is favoured with some peculiarities of climate. At a fair distance from the back of the town rise the Purbeck Hills, in shape like a horse shoe, and each extremity ending in cliffs; these protect it from the heavy inland and sea fogs which are undesirable features of much of the southern coast of England, and from which Swanage is therefore very free. The town is undeniably very picturesque, and from its older centre has thrown out streets of handsome modern houses radiating up the hills behind it; the old part, with its houses of soft-coloured, pearly-grey stone, and roofs of dark flagstones (splashed with patches of yellow stone-crop and house-leek), winds along the surface of the hills in pleasantly irregular undulations. The background heights and surrounding cliffs are covered with a short dark-green herbage, which stretches down to the yellowish-grey sands, and form a harmonious piece of tender neutral colouring throwing up the rich and sparkling tints of the sea, which seems to glow amidst its delicately toned surroundings, and to glitter like a gem.

The ancient tower of the parish church watches over the bay, stern, gaunt and four-square; it is probably some 600 years old, without buttress or ornament, and doubtless, as asserted, was built for a watch-tower and beacon. However, the coast's best protection in past years were its rocks on which, below Peveril Point, 100 vessels of the Danes were shipwrecked, and Alfred gained his victory 1000 years ago. Near the beach is a granite column commemorating this event, and bearing on its summit five cannon balls, surely a most irrelevant ornament; this column is not so hideous as an obelisk on the outskirts of the town to the inevitable memory of "Albert the Good." To see more of the place we must walk up through the modern streets of Swanage, which are as hilly as those of Bath, and guided by the profuse direction-stones let into every corner, find our way to Durlston Head. The land leading to it has been bought by Mr. George Burt, an ex-sheriff of London, and local benefactor. It is a wild piece of ground stretching west of Swanage, across the tops of the cliffs; here money has been lavishly poured out in preparing for coming building operations, which would seem to indicate intentions of rivalling Bournemouth at some future date.

Ten miles of walling have been built and five miles of fine broad roads made; millions of trees and shrubs have been planted in belts and patches. The place, naturally, is now looking scarred and in the rough, but it commands magnificent sea views. A road leads to "Durlston Castle," a huge and most solid structure built by Mr. Burt, on Durlston Head itself, at a level of some 200 feet above the sea This is being fitted up as a hotel, and on three sides of it has fine sea-views; with its terraces and platforms it is already one of the lions of the coast. Let into one side of its walls (going down towards the platform where the "great globe" is), are large boldly-carved slabs on which are set out the duration of the longest day in various parts of the world; the variation of time caused by longitude; the convexity of the ocean and other matters of scientific or practical interest. The "great globe" itself is certainly a most curious and original object; it is constructed of Portland stone, weighs forty tons and is ten feet in diameter. On it, in high relief, are carved the continents, oceans, etc., the benches surrounding it are placed in the proper positions of the various points of the compass and lettered accordingly. These singular ideas are carried out with great perfection; it having been found that holiday-makers were beginning to write their names on the globe, in their usual imbecile way, a large slab has been placed in the wall close by headed with this inscription: "Any persons anxious to write their names will please do so on this stone." This excellent suggestion might well be imitated by possessors of objects of interest which have a surface tempting to the ubiquitous excursionists knives and pencils. Leaving the globe, a broad gravelled path, cut on the edge of the cliffs and guarded by a low wall, leads down to the caves of Tilly Whim. A tunnelled entrance has been sunk by Mr. Burt descending into one of the caves and on to the shore. These caves were formed by the quarrying for Purbeck stone; from time immemorial till recently they have supplied the whole country-side with rick and sink-stones, and from here came the stones for Corfe Castle, an immense feudal fortress near Swanage. Stepping out of the caves one is struck by the magnificence of the great sombre rocky cliffs, and the boulder-strewn shore beaten by a sea, which at times leaps over it. The sight is most imposing, and does not need the Shakespearian lines carved in gigantic letters on the face of the rock to indicate its undoubted elements of beauty. But the Genius of the Place affects rock-inscriptions, and the "graffiti" of Durlston Head and Tilly Whim may puzzle future generations of antiquaries, and be finally classed with the Sinaitic. The caves have many stories attached to them, and were used by smugglers. The great Gulliver, that hero of all Dorset smuggling legends used them in the palmy days of the French War. He conducted his operations on the largest scale, and his memory still lingers amongst the old people. It is said that on his death-bed he attempted to keep the Spirit of Darkness from seizing him by barring up the windows, but in vain, for an old retainer broke the news of his death to his friends in the laconic words "He has got'un."

Above Tilly Whim is the Anvil Point Lighthouse, and further along the cliffs are Dancing Ledge and St. Alban's or St. Aldhelm's Head; here the scenery is very bold and fine, particularly so in stormy weather. The edges of the cliffs are rich in flowers; in July the great umbels of the

sea carrot (*Daucus maritimus*), of a colour between pale pink and light fawn, are very striking. Behind the light-house, in a space less than five feet square, the writer found no fewer than six of the British thistles—viz., *carduus nutans*, *carlina vulgaris*, *lanceolatus*, *acaulis*, *arvensis*, and *tenuiflorus*. If the district is botanically interesting, it is more so geologically. The Purbeck Beds are noted for their layers of fossil vegetable earth (dirt-beds), enclosing roots, trunks, and branches of cycoids and conifers, the beds themselves consisting of argillaceous and calcareous shales and fresh water limestones and marbles. The quarries of the famous Purbeck stone lie chiefly about Langton Matravers; they are several hundreds in number, and are worked according to demand for particular qualities of stones, the marble ridge being only worked from when wanted. The quarrymen are an exclusive and privileged race, the "Free Marblers of Purbeck" claiming a Charter from Edwardian days; birth or marriage are the only recognised means of entering this select society, which has its "officers" and "freemen." On Shrove Tuesday they transact their business, and formerly kicked a football from Langton, through Corfe, over the Heath to Ower; now the football is carried, and with it a pound of pepper to the Lord of the Manor, as an acknowledgment in respect of the way to Ower. A most interesting walk from Swanage is over Ballard Down to Studland, whence the finest possible view may be obtained of the silvery stretches of Poole Harbour, with darkly-wooded Brownsea Island lying in the midst of it. Studland Church contains some good Norman carving, and on one of the four bells in its tower is the inscription, "Draw near to God, C.P., 1605." At Standfast Point, beneath the Downs, on the way to Studland, is the curious rock called "Old Harry;" it is a square detached pillar-like rock, separated by a reef and a narrow channel from the main land. A mile from Studland, on a mound about 90 feet high, is the Aggleston, a great block of red sand-stone, weighing many hundreds of tons, the upper portion of it is overhanging, and to the whole a Druidic origin has been ascribed. Half way between Swanage and Wareham is Corfe Castle (already mentioned); it is one of the most extensive ruins in England, and beautifully situated on a very lofty green mound. Here Lady Bankes made her gallant defence against the troops of the Parliament, though she had at first but five men in the garrison, and at no time more than forty, till the siege was raised by the Earl of Carnarvon, August 4th, 1643. It was of her husband, Sir John Bankes, who was Chief Justice of the Common Pleas, that Lord Strafford wrote: "Bankes hath been commended that he exceeds Bacon in eloquence, Ellesmere in judgment, and Noy in law." Wareham is only a half-hour's train journey from Swanage, and has claims of great interest for an antiquary. On three sides it is entirely surrounded by ancient earth-works which are high and broad, and being covered with a short fine grass are most pleasant to walk on, and from them are pretty views of the old town, which is situated in a plain; the land immediately outside the earth-works is under cultivation, but shades off into wild, broken, heath-covered ground with a belt of jagged hills.

There are three old churches in Wareham, and the chief one has a remarkable east window; the chance passer-by cannot also fail to note the exquisite iron scroll-work which supports the signs of nearly every inn and public-house; the boldness, beauty and variety of this true art-work is quite equal to some of the best specimens which remain in remote parts of Surrey. The view from the bridge over the Froom is charming by its contrast of banks and meadows of green pasturage with fine trees, amid the rougher moorland landscape, across which Guthrum the Dane must have passed on his way to surprise and rout the few dispirited men who were gathered round the banner of the Golden Dragon. All these spots are within an easy reach of Swanage; as is also (by steamer) the Isle of Wight; Bournemouth, Christchurch, and Poole are easily visited, and the many villages in the Island of Purbeck have all their points of interest and fine scenery. In conclusion, of Swanage itself it may be added, that the gently-sloping, sandy beach offers first-rate bathing; there is a good hotel, and abundance of good lodgings, and the town drainage was carefully reorganised some two or three years ago. All these are very important additions to the attractions and healthiness of a place, which once visited and known is pretty sure to please and benefit one.

XXXVI.—LUNDY ISLAND.

By Alfred J. H. Crespi, of Wimborne.

It requires some boldness to include among health resorts the tiny island that shows up in the interminable waste of waters, west of Ilfracombe and Barnstaple, sometimes only a faint blue streak on the horizon, at others, looking, magnified by the mist, absolutely imposing and of vast but uncertain size. If one half the charm of a health resort consist in novelty, and the other half in uncontaminated fresh air, Lundy can claim a high place on the yearly lengthening list. As for novelty, I dare confidently assert that not the loneliest seaside village or the newest of new watering places can compare with it. All alone it stands in its glory, little affected by the flight of the centuries, innocent of trees, far beyond the sound of railways, and a few years ago, before the cable was laid, it still rejoiced in infrequent posts and in about as precarious communication with the rest of the kingdom as any place so near could have, and still remain part of the British Isles.

Visitors to Instow and Ilfracombe are generally fortunate enough, sooner or later, to catch a glimpse of the long, low line, far away on the western horizon, which they are told is Lundy. At a distance of twenty-four miles, it seldom looks more than a nebulous line, slightly raised above the water, although in some states of the atmosphere it towers above the water and seems quite near at hand; on closer approach it is seen to stand up grandly—a stupendous granite mass, four miles long, three-quarters of a mile wide, and from four hundred to over five hundred feet high.

Its configuration is singular, and its long diameter points nearly due north and south, while its eastern slopes, precipitous enough to make them interesting and romantic, are only one degree less striking than its western sides, where walls of rock rise in perpendicular steps, sixty and eighty feet at a time. The western side is particularly imposing; and were Lundy more accessible, it would have tens of thousands of visitors; but it has no harbour, and no landing pier or stage, and though the beach, at its south-eastern extremity is good as far as it goes, it is not always accessible or safe. Sometimes furious seas roll upon that beach, as though they would wash the very island itself away, and Lundy is then completely cut off from all communication with the mainland, except by the telegraph, which a few years ago was laid down between Hartland, on the Devon coast, and the South Point. Off Lundy the anchorage is excellent

in westerly gales, and then, especially if the storm lasts some days, numbers of fine steamers and splendid ships with whole fleets of skiffs and tugs take shelter under the lee of the island, and there they stay, till with a shift of wind to the east, they are off to some less exposed spot.

I have lived on Lundy three years and a half, and after much hurrying to and fro and a long residence in great cities the contrast was startling. Quiet and leisure I had in plenty, for my professional duties were a sinecure; but, cut off from conflict and competition, the inclination to work and to make the most profitable use of my time was wanting, and never did I do less, never did I get through fewer books. No! whatever poets may say to the contrary, the man exposed to the storms and distractions of life works hardest and does best. Rural retirement is more captivating to the imagination than in reality. I used to listen to the piercing shriek of the restless wind, stroll about the island, exchange a few words with the residents, and when evening came I was sufficiently tired to feel that I had earned a good night's sleep in return for my arduous labours. The more a man has to do the more time he commonly finds to undertake fresh work; the thinker, or he who aspires to be reckoned such, must live among men and be sharpened by intercourse with his fellows; even the poet must not go to the desert for inspiration, and Lytton in accounting for Leonard Egerton's failure to produce a second masterpiece gives as an explanation the mistake he made in burying himself in a remote western village. I am not even sure that natural history would gain much at the hands of a recluse, whose theories were not corrected and observations tested by critical and sceptical colleagues.

Lundy is in many ways noteworthy; its chief attractions are its configuration, climate, bird-life, and vegetation: to say nothing of its history: the last not very eventful it may be, but going far enough back to invest it with some interest. On the south point, overlooking a narrow and dangerous neck of land, which connects the main portion of Lundy with Lametry, stands a small castle—rugged, ancient, and gloomy—once the stronghold of a Norman baron, and still called "The Castle." Its original lord and founder was a certain De Marisco, this is said to be a corruption of De Montmorency. The island, according to tradition, was granted, many centuries ago, to the Knights Templars, who, however, never took possession of it. Then it passed from one noble to another, was the scene of much petty fighting between Welsh and Irish, and finally, fifty or more years ago, came into the possession by purchase, of the late William Hudson Heaven, a quiet, amiable country gentleman, who made it his home for many years, and there died not long ago. The present owner is his son, the Rev. Hudson Grosett Heaven, M.A., late of Trinity College, Oxford, an able and accomplished man of scholarly tastes, who has the rare felicity, in the south of England at any rate, of being absolute lord of all he surveys, without an equal or rival for many miles.

The top of the island is an extensive and tolerably level plain, sloping slightly towards the north and east, with no trees, no hedges, and no shelter. This absence of shelter is a serious drawback and diminishes the value of the land for agricultural purposes, for from the comparative mildness of the winter and the absence of severe frost, large quantities of excellent early vegetables might be grown for the Bristol markets, were there only good protection. Perhaps, were sufficient expense incurred, some shelter might be found in the combes on the eastern slopes, and vegetables of excellent quality could be grown a month earlier than on shore.

After the end of March, white frost is rare. In March, 1878, the lowest reading was 32° F., in April, 33° F., and in May, 39.5°. In March, April, and May, 1879, the readings were respectively 29.5°, 30.5°, and 36.5° F., and in 1880, in the same months, the minima recorded were 36.0°, 39.0°, and 38.5°. The mean temperature of the Island must be about 50.5 F., its principal characteristic being the mildness of the nights, especially in spells of severe weather on shore, but the summer maxima reduce the annual mean below the figures, which the mild winter would lead one to expect. Unfortunately the elevation of the island and the want of shelter from wind, counterbalance in some measure the exceptional advantages which the absence of low temperatures would give.

The south half has long been cultivated; there the grass is smooth and green, and the crops are of superior quality; the northern half remains in a state of nature, with shallow soil or bare rock, and more lichen and moss than turf. The slopes of the island, which are locally called *sidelands*, are, in places singularly beautiful and attractive; in others, principally, though not wholly, on the west, majestic, and impress the few people who have the opportunity of seeing them as surpassing in rugged, untamed grandeur anything to be seen in the South of England, not excepting the precipitous rocks near Land's End, which cannot be much more than half as lofty and look insignificant in comparison. On the slopes, well under the shelter of the mass of the island, but some distance above the water, the soil is, in places, deep and is contained in pockets, where it has accumulated, and there many species of wild flowers luxuriate, and attain splendid proportions.

Nearly all animals well repay attentive observation, and speaking broadly differences of temper and habits are very pronounced. Horses, cows, dogs and cats all have curious peculiarities and no two members of the same species have the same taste. A cat in this town formed the habit of eating raspberries, and it was most entertaining to watch the tiny creature climbing the canes and creeping along the wires picking off and eating one fairly ripe fruit after another. I need hardly say that the cat's owners, though proud of its originality, would have preferred it to eat somebody else's berries. A little black cat, now in my possession, is strangely fond of ripe melon and cannot be kept off the sideboard if one is there—he eats three or four small slices at a time with great gusto, and he and his mother often leave other food for soft dry bread, which they get through in large quantities; he also enjoys drinking out of the bedroom jugs quantities of water very large for such a mite. Mr. Charles Augustus Murray in his delightful "Travels in North America" mentions an incident showing the affection sometimes subsisting between animals apparently having nothing in common. He says that at Bordentown he found the whole village in a state of wild excitement, and was informed that a menagerie was coming. Of course he went to see it and found it uninteresting with the exception of a very fine black-maned African lion and a young female elephant, which had been saved from the wreck of an English ship; the lioness had taken such a huge fancy to a fine bulldog that she could not be induced to leave the sinking vessel until he had been compelled to jump overboard, when she at once followed; the tender pair were of course after that not separated. Now the great charm of Lundy is the opportunities it offers of studying natural history, for its speciality is its

wild birds, which once abounded. In former days, when they rose they filled the air with their discordant cries, but long before I took up my residence on the island their numbers had greatly diminished, and though protected, as much as possible, by the squire and his sister, serious inroads have been made upon their numbers, and they no longer rise in the dense clouds reported by earlier visitors. In April they *come in*, and before long almost cover the rocks and the more inaccessible headlands, and a little later they commence to lay. The species commonly met with are several sorts of gulls, guillemots, shags, razor-billed auks, puffins, and a few, alas! only a very few gannets, that noblest of British sea-birds, which darts like a ray of light far below the watcher's feet and not much above the water. It is said, though I cannot vouch for it, that Lundy is the lowest latitude in which the Solan goose lays, though that distinguished oriental scholar and traveller—Dr. W. F. Ainsworth—has seen it flying along in its characteristically majestic fashion, on the coast of Portugal. Gannets choose open ledges, and most of them, almost of necessity, lay where daring climbers can get their eggs. The temptation is too great, and as the work of destruction never ceases, the wonder is that any escape, what with the depredations of the birds, who can often be seen sitting in most contemplative and philosophical fashion, with half an egg shell impaled on their beaks, what with the rats, and what with the assiduous hunts of the islanders, the sailors and the pilots. I do not want to accuse seabirds of being cannibals, and eating their own eggs, that would be too cruel a charge to make, but do they not eat the eggs of offending friends? At any rate they are often seen sitting reflectively, with the remains of an egg on their beaks; and sharp eyes have before now seen a guillemot with a guillemot's egg thus impaled. Truly the eggs in the season have many enemies to face. Puffins generally lay their eggs, which much resemble those of the domestic fowl in size and shape, though not identical in colour, in burrows, and consequently many escape. The razor-bills also choose obscure and unsavoury nooks behind huge masses of rock that have fallen from the top of the island: but gulls and guillemots are less acute and far-seeing, and deposit their eggs in full sight of the egg gatherer, while Solan geese select by preference bare ledges, not particularly difficult to reach, and few of their eggs are hatched out. The largest egg is the gannet's, and it usually fetches sixpence, but the most brilliantly coloured is the guillemot's—which is green, white, or blue. Nests are not made, except very rude ones by gannets and gulls, and a little rubbish is scraped together by some of the puffins; in short, sea birds do not excel as nest builders.

The tameness of the birds at the breeding-season takes one by surprise, and some of the smaller species actually remain on their eggs until they are driven off. They not unnaturally resent the attempt to remove them, opening their formidable beaks, and snapping with right good will at the fingers of the egg-thief. Of all quaint little creatures, none surpasses the puffin with its comical physiognomy and red colouring, so much more vivid in life and in its native haunts than in museums, where, however skilfully and faithfully the bird-stuffer does his work the student of nature is painfully struck by the contrast, missing that indescribable something which life alone can give. Sea birds' eggs are not bad eating when boiled a long time, but they have rather a strong flavour, and are useless for delicate high-class cooking. As for the flesh of the birds, though not absolutely uneatable, especially in a meat pie, there is something unpleasant in the thought of eating it, and few birds are used to satisfy the human appetite on our English coasts, though the hardier and less squeamish Scotchman does not despise them preserved in salt. Of land birds Lundy has a longer list than one would expect—blackbirds and song thrushes, robins, white-throats, a few cuckoos, sparrows, chaffinches and other common species being at all seasons fairly numerous, while in severe weather considerable flocks of tender native birds cross from the mainland. In addition to the foregoing, plovers, curlews, peregrine falcons, Cornish choughs, ravens, crows, gosshawks, and buzzards are seen in small numbers, a pair or two of each species permanently residing on the island. The peregrine falcons of Lundy have always been held in high repute for hawking, and even at the present day young falcons are sent away for this purpose. An occasional eagle has before now condescended to alight on the island for a short rest.

No more favourable place than the Lundy sidelands could be found in June and July for the study of birds. What life! what movement! what conflicting interests! Talk of the lower animals not being worth studying, why, they are sometimes more intelligent than men, at any rate more interesting, and have they no memory? What about the very learned dog which not long ago appeared before Mr. O'Donnell in the Dublin police-court as a witness in a dispute as to his ownership? A Mr. Burke claimed to be his owner against a man named Smith, who had had the animal since the previous August, when Mr. Burke said he had lost him. Mr. Burke, who had been in India, said he taught the dog Hindustani and Tamil, and the dog, on being brought into court and addressed by him in those languages, immediately responded, doing several things he was desired, and he was therefore restored to Mr. Burke.

In mild winters Lundy weather is of a broken spring-like character and favourable to bird and insect life, but I never heard of any swallows being seen there at that season. Now as is well known, Gilbert White continued, in spite of certain disclaimers and evident doubts, to believe that the hirundines passed the winter in sleep, and he also credited the cuckoos with hybernating. Would a residence on Lundy have satisfied him? The other day a writer in one of the papers actually said that he did not believe that the question was settled in favour of migration, and he mentioned that four people had heard what they thought was a cuckoo in mid-winter. I may remark that the anatomical peculiarities of these birds would not be compatible with hybernation, while it is certain that not a winter would pass without many torpid specimens being found. But though birds may not hybernate many mammals do so regularly, and some others have a knack of lying *perdu* as it were for days. A marmot, in its winter sleep, has been rolled along like an inanimate ball, and it then seems unconscious of pricks or pinches, while the fluids in its tissues are nearly exhausted and its blood becomes thicker than ordinary, in short all the functions and habits of animals deserve investigation, and the bird lover should really pitch his tent on Lundy for a few months.

Although the rocks look so precipitous, and in places rise in abrupt ledges four hundred and even four hundred and fifty feet from the water, long practice and holding a rope in the hand, securely fastened to a crowbar driven into the ground, or firmly attached to a projecting point of rock, will enable a steady head and a keen eye to explore almost all the ledges, comparatively little of the sidelands being

absolutely inaccessible. Nor is this amusement so dangerous as might be supposed, though lives have occasionally been lost. Ladies soon become expert climbers, and find great enjoyment exploring the nooks and crannies of the mysterious bays of the west and north-west.

Lundy, as I have explained above, has become a favourite shelter for thousands of ships in the course of every year, and it has probably saved many thousands of lives and hundreds of vessels. Unfortunately, in fogs, it is often the cause of loss of life and destruction of property, and many a ship has gone down on the dangerous reefs and iron-bound sides. On the morning of Tuesday, February 6th, 1877, during my residence on the island, a large steamer, the *Ethel*, of Sunderland, struck on a dangerous rock on the west side, not far from the battery. The mate, a Scotchman, named John Lawrence, after a terrible struggle for life, swam ashore and was saved; his escape was simply miraculous. Had he not escaped, it is very possible that the steamer to which he belonged would have been lost sight of, and no information would ever have reached the world as to its awful fate.

The population never can have been large, nor can fishing have brought immigrants from Cornwall and Devon. The absence of a safe harbour is a fatal drawback, for though the anchorage is excellent and shelter can generally be found in the roughest weather, for many years there has not been, and perhaps there never was, any place where a small craft could count on absolute safety in all states of sea and wind; in other words, vessels could never have belonged to the island and stayed near it. The shellfish is good, and a band of rugged Cornish fisher-folk, from the remote coves of Land's End and Sennen, usually come over for some months, every spring and summer, and, by means of their lobster pots, manage to get large hauls, which they take over to Ilfracombe or Instow for the London market. There is no life of greater peril and exposure and more continuous labour than the fisherman's, and its rewards are small; the poor fellows losing their sleep and working like slaves, and often ending by perishing in storms, and all in return for very small wages. But it must have a certain inexplicable fascination, at any rate no dearth of fishermen is feared, though the men who follow the calling do not seem particularly unhappy, and find a strange pleasure in relating their rather unromantic and monotonous experiences of wet and cold.

On the western side of the island there are many singular clefts or rifts, which look as though there had been some terrible convulsion of nature; this part of the island is called the Earthquake, and tradition relates that these clefts date from the catastrophe of Lisbon. I am no geologist and must express an opinion with extreme caution, but any connection between these rifts—this splitting of the granite, these faults, as I suppose they would be technically called, and the Lisbon Earthquake is as improbable as between them and the Battle of Waterloo. None the less are they of singular grandeur, and among the most wonderful of the many marvels of Mr. Heaven's little kingdom. In other places, too, the rocks are fantastically contorted, and look as though they had been uncouthly carved by laborious South Sea Islanders or Egyptian colonists, and these natural sculptures are locally known by such appropriate names as the Templar.

The antiquities of Lundy are not remarkable, and, the remains of the small castle excepted, offer little to attract the antiquary. Legends have been handed down of a dense population in ancient days, and of towns, villages, and churches, but these seem to have little to rest upon. Some brass guns, thrown down from an old battery on the sidelands, were said to be visible in the water, at certain states of the tide on the east side, but I never saw them, though I often looked for them. Some kistvæns were found many years ago, but no description was given of them, and they are totally gone. A quarter of a century ago, too, some men, cutting a trench for the foundation of a wall, came upon a curious grave, evidently of great antiquity, enclosing a skeleton, and the remains of eight or nine other human bodies were lying near. The skeleton in the grave is said to have measured eight foot three, and a second was also of abnormal size. The improbability that the correct measurements were obtained is so obvious that few scientific men will accept these figures as reliable. A lady, generally residing on the island, though temporarily absent, assured me that no mistake had been made, and that I could accept the measurements. Unfortunately the attention of antiquaries was not drawn to the matter, and the skeletons were buried in the Churchyard by order of the late squire. Some rude beads, apparently of glass, were found in or near the graves, and were preserved, and these have been submitted to a learned friend of mine who has pronounced them Danish, but of no special value. The largest of the skeletons was enclosed in a rude stone grave, not a carefully constructed stone coffin, although a stone had been hollowed out for the head and another for the feet. If the beads were Danish it is natural to assume that the bodies were those of Danes, and a curious inquiry might arise as to whether the ancient Danes buried their dead in the fashion described. Of course the length of the skeletons is startling.

Although a member of what is by courtesy reckoned a scientific profession, one of the others I suppose being civil engineering, and a third the army under modern regulations, I can never get up the smallest enthusiasm in scientific pursuits, at any rate in geology; true, I delight to watch the merry birds, because they are so beautiful; but art—painting, music, and architecture—gives me far deeper pleasure, and so I have not attempted to describe the geological, botanical, and insect features of Lundy, although I am told they are interesting. But I should like to see the Woolhope Club clambering up and down the rocks, and rushing frantically on some find of special beauty. It amuses me to see high wranglers and public examiners gazing with intense delight on some almost microscopic beast or leaf, and absolutely catching their breath as the truth flashes upon them that it is very interesting. "Bone," ejaculated a tall and stately clergyman of national reputation, as he handed me a rounded pebble, "bone rolled round by the aboriginal races of the country." "Stone," I rejoined, when I had looked at it "rounded by attrition on the sea shore." "So it is," replied the Reverend Fellow of the Royal Society, "I had not properly examined it." Mr. Heaven could not do better than invite some famous field club to an *al fresco* existence for a week among the rocks of Lundy: what vegetable treasures they would unearth; what discoveries would make their visit memorable in scientific annals, and how poor Thomas Edward, of Low Shore, Banff, would have enjoyed passing a few months on Lundy; but how little the general public would see to justify such enthusiasm! The naturalist's pleasures are quiet and unexciting, and not easily shared by the uninstructed.

The present population is small, and though it rises and

falls a good deal, has of recent years, rarely exceeded fifty, most of whom are connected with the extensive farm, comprising nearly all the cultivated land of the island; others belong to the lighthouse service, and a few to the squire's family. Some years before I took up my residence on the island, extensive quarrying operations were going on, and a large population was living there, but no granite is now being worked; the stone, however, is said to be excellent. Accommodation for visitors is scarce, and the squire does not like his little kingdom to be invaded by strangers. In summer a fast steamer crosses most weeks from Ilfracombe, and stops a few hours, and in this way an opportunity is afforded of exploring the place; a skiff also crosses weekly from Instow.

Difficult would it be to find another spot so cut off from the busy world, so interesting in its way, and so difficult of access. When I used to cross to Instow, I felt that I was then in the bustle of modern life; though the first time I went to Lundy from Birmingham, directly after a journey to New York, Instow, at which I was kept twelve days by the high seas, looked like the *Ultima Thule* of civilised life. Since I ceased to reside there, eight years ago, I have not set foot upon it, and the trouble and uncertainty of getting to and leaving Lundy sufficiently explain my long absence, although my interest in it is undiminished. I often hear from some of the residents; and very great changes have of late been made, but not of such a character as to require any modification of what I have said above.

XXXVII.—BOSCOMBE.

By our Special Medical Correspondent.

The opening of the new pier at Boscombe, on Monday, July 29th, is unquestionably the greatest event in the history of that rapidly-rising watering place. It was witnessed by crowds so vast, that the public interest was evidently keen, while the weather was simply perfect. Many of our readers probably do not know that Boscombe is an extension of Bournemouth, halfway between the latter and Southbourne-on-Sea. Sixteen years ago Boscombe consisted of a few huts and a couple of tiny shops, nothing more, and now, like Washington, it is a city of magnificent distances, with miles of broad, noble new roads, hundreds of handsome houses, and preparations for building on a colossal scale. Indeed, we were told on good authority that the houses now being put up represent over £150,000. At present many of the roads are not built up; but in ten years we venture to predict that there will hardly be an unoccupied site, and that the population will have quadrupled. The distance from Bournemouth was so considerable that it was thought desirable to build a pier and to make good approaches to it, and a wild but most picturesque chine was selected for the purpose. The pier has cost £12,000, and never was money more judiciously laid out, never was work better done, while the spot chosen has the greatest natural and artificial advantages, and could hardly be matched by anything in the neighbourhood.
